White light can be produced by many approaches; one of the most common and easiest ways is the combination of the yellow-emitting phosphor made of cerium doped yttrium aluminum garnet (YAG:Ce$^{3+}$) (Ref. 1) and blue-emitting GaN chips. Although this kind of white-light blending method has been well used for a few years, some problems have existed; one of them is that the variety of hue is insufficient compared with the white light mixed from three primary colors. To circumvent this disadvantage, the red, green, and blue multiphased phosphors or single-phased dichromatic phosphor consisting of two emission bands in the green and red spectral regions are employed to generate white light under ultraviolet (UV) or blue light-emitting diode (LED) chip excitation, respectively. However, in the three-converter system, the blue emission efficiency is poor because of the strong reabsorption of the blue light by red or green-emitting phosphors. Therefore, many efforts have been made to develop the single-phased white-emitting phosphors which are based on the mechanism of energy transfer from Eu$^{2+}$ to Mn$^{2+}$ (abbreviated as ET$_{Eu-Mn}$ hereafter) that has been studied actively in the past few years.\(^2\)\(^-\)\(^6\) In this letter, we have demonstrated that the white light could be generated with combination of tunable yellow green-to-orange red emitting phosphor Ca$_2$MgSi$_2$O$_7$:Eu$^{2+}$,Mn$^{2+}$ (CMSO:Eu,Mn) and violet-blue (380–420 nm) radiation source. We have also proven that a warm white light can be achieved by increasing the contents of Mn$^{2+}$.

The silicate compound of Ca$_2$MgSi$_2$O$_7$ with akermanite structure was reported to crystallize in the tetragonal crystal system with the space group $P-4_2/m$ and the lattice parameters $a=7.8338(6)$Å and $c=5.0082(5)$Å.\(^7\) Three crystallographically independent cation sites, namely, one Ca$^{2+}$, one Mg$^{2+}$, and one Si$^{4+}$ exist in the crystal lattice. The Ca$^{2+}$ ion is coordinated by eight oxygen atoms with an average Ca–O distance of 2.573 Å, and both Mg$^{2+}$ and Si$^{4+}$ cations were reported to occupy in the tetrahedral sites with an average $M$–O distance of 1.916 Å ($M$=Mg) and 1.624 Å ($M$=Si), respectively.\(^7\) In view of the effective ionic radii of cations with different coordination numbers,\(^8\) we have predicted that Eu$^{2+}$ and Mn$^{2+}$ prefer to occupy the Ca$^{2+}$ and Mg$^{2+}$ sites, respectively, because the ionic radii of Eu$^{2+}$ (1.25 Å) and Mn$^{2+}$ (0.66 Å) are compatible with those of Ca$^{2+}$ (1.12 Å) and Mg$^{2+}$ (0.57 Å). Nevertheless, the Si$^{4+}$ site (0.26 Å) is too small for the substitution of Eu$^{2+}$ and Mn$^{2+}$ to take place. High temperature solid-state reactions were employed to synthesize CMSO:Eu,Mn. Powders of high-purity (all in 99.99%, Aldrich Chemical Co., WI, USA) CaCO$_3$, MgO, SiO$_2$, MnCO$_3$, and Eu$_2$O$_3$ were weighed in stoichiometric proportions, thoroughly ground and mixed in an agate mortar, pressed into pellets, and calcined at 1300 °C for 8 h in an inner alumina crucible that was contained in a covered outer alumina crucible filled with graphite powder. Afterwards, the product was reduced further at 900 °C for 3 h under an atmosphere of 5% H$_2$/95% Ar. The phase purity of all the samples was characterized and evaluated by powder x-ray diffraction (XRD) analysis by using a Bruker AXS D8 advanced automatic diffractometer with Cu $K_{\alpha}$ radiation operated at 40 kV and 20 mA. Figure 1 shows the XRD profile for the optimized composition (Ca$_{0.99}$Eu$_{0.004}$)$_2$(Mg$_{0.65}$Mn$_{0.35}$)Si$_2$O$_7$, which agrees very well with that reported in Ref. 9, indicating that both of the host

White light generation under violet-blue excitation from tunable green-to-red emitting Ca$_2$MgSi$_2$O$_7$:Eu,Mn through energy transfer

Phosphors Research Laboratory, Department of Applied Chemistry, National Chiao Tung University, Hsinchu 30010, Taiwan

(Received 19 December 2006; accepted 14 March 2007; published online 16 April 2007)

Yellowish green-to-orange red emission can be generated by energy transfer from Eu$^{2+}$ to Mn$^{2+}$ in the Ca$_2$MgSi$_2$O$_7$ host matrix. Eu$^{2+}$-doped Ca$_2$MgSi$_2$O$_7$ shows a broad green emission band centering at 528 nm and Mn$^{2+}$-doped Ca$_2$MgSi$_2$O$_7$ exhibits a red emission at around 602 nm. The authors have demonstrated that the mechanism of energy transfer from Eu$^{2+}$ to Mn$^{2+}$ in Ca$_2$MgSi$_2$O$_7$:Eu,Mn phosphor is a resonant type via a dipole-quadrupole mechanism. They have also shown that the white light with varied hue, depending on contents of Mn$^{2+}$, is generated by combination of predesigned emission wavelength-tunable Ca$_2$MgSi$_2$O$_7$:Eu,Mn phosphors and violet-blue light source. © 2007 American Institute of Physics. [DOI: 10.1063/1.2722670]

White light can be produced by many approaches; one of the most common and easiest ways is the combination of the yellow-emitting phosphor made of cerium doped yttrium aluminum garnet (YAG:Ce$^{3+}$) (Ref. 1) and blue-emitting GaN chips. Although this kind of white-light blending method has been well used for a few years, some problems have existed; one of them is that the variety of hue is insufficient compared with the white light mixed from three primary colors. FIG. 1. (Color online) XRD profile of (Ca$_{0.99}$Eu$_{0.004}$)$_2$(Mg$_{0.65}$Mn$_{0.35}$)Si$_2$O$_7$ showing good agreement with that reported in Ref. 9.
structure and single-phased composition are retained even at high codoping level of Eu\textsuperscript{2+} and Mn\textsuperscript{2+}.

The measurements of photoluminescence (PL) and photoluminescence excitation (PLE) spectra for CMSO:Eu\textsubscript{2+} and Mn\textsubscript{2+} doped Ca\textsubscript{2}Mg\textsubscript{1−x}Mn\textsubscript{x}Si\textsubscript{2}O\textsubscript{7} phosphors were performed by using a Spex Fluorolog-3 spectrofluorometer (Instruments S.A., NJ, USA) equipped with a 450 W Xe light source and double excitation monochromators, and the details have been described in our previous work.\textsuperscript{3} Figure 2(a) depicts the PLE and PL spectra of Eu\textsuperscript{2+} and Mn\textsuperscript{2+}-doped Ca\textsubscript{2}Mg\textsubscript{1−x}Mn\textsubscript{x}Si\textsubscript{2}O\textsubscript{7}, respectively. In solely Eu\textsuperscript{2+}-activated system, the PL spectrum shows a broad green emission band centering at 528 nm attributed to the 4f\textsuperscript{6}5d\textsuperscript{1}(t\textsubscript{2g}) \rightarrow 4f\textsuperscript{7}(s\textsubscript{g}) transition of Eu\textsuperscript{2+}, and the observations in the PLE spectrum situate between the UV and blue region consisting of unresolved bands due to the 4f5d multiplets of the Eu\textsuperscript{2+} excited state. However, in the solely Mn\textsuperscript{2+}-doped system, the PL spectrum exhibits a broad red emission around 602 nm which is ascribed to the spin-forbidden 4A\textsubscript{1}(4S) \rightarrow 4F\textsubscript{3+}(4I\textsubscript{g}) transition of Mn\textsuperscript{2+} and the PLE spectrum contains several bands centering at 325, 350, 408, 425, and 500 nm, corresponding to the transitions of Mn\textsuperscript{2+} from 4A\textsubscript{1}(4S) to 4E\textsubscript{1}(4D), 4T\textsubscript{2}(4D), 4A\textsubscript{1}(4G), 4E\textsubscript{1}(4G), 4T\textsubscript{2}(4G), and 4F\textsubscript{3+}(4I\textsubscript{g}) energy levels, respectively.

As also shown in Fig. 2(a), based on the observed significant overlap between the excitation spectrum of Mn\textsuperscript{2+} and emission spectrum of Eu\textsuperscript{2+}, the effective resonance-type energy transfer is expected to take place from Eu\textsuperscript{2+} to Mn\textsuperscript{2+}. The PL spectra obtained by excitation at 381 nm for Ca\textsubscript{0.99}Eu\textsubscript{0.01}Mn\textsubscript{2+}Si\textsubscript{2}O\textsubscript{7} with varied Mn\textsuperscript{2+} dopant contents are presented in Fig. 2(b) and it can be visualized clearly that the intensity of Eu\textsuperscript{2+} sensitizer was found to decrease remarkably and simultaneously as the contents of Mn\textsuperscript{2+} increased gradually. The observed energy transfer efficiency (\(\eta_T\)) from Eu\textsuperscript{2+} to Mn\textsuperscript{2+} has been discussed by Pau lose \textit{et al.}\textsuperscript{10} and can be expressed by

\[ \eta_T = 1 - \frac{I_S}{I_{S0}}, \]  

where \(I_{S0}\) and \(I_S\) are the luminescence intensity of the sensitizer (Eu\textsuperscript{2+}) with and without activator (Mn\textsuperscript{2+}) present. The \(\eta_T\) from Eu\textsuperscript{2+} to Mn\textsuperscript{2+} in Ca\textsubscript{0.99}Eu\textsubscript{0.01}Mn\textsuperscript{2+}Si\textsubscript{2}O\textsubscript{7} was calculated as a function of n and is represented in the inset of Fig. 2(b). With increasing Mn\textsuperscript{2+} dopant content, the \(\eta_T\) was found out to increase and reach the saturation when \(n > 0.2\).

Based on Dexter’s energy transfer formula of multipolar interaction and Reisfeld’s approximation, the following relation can be obtained:\textsuperscript{11}

\[ \frac{\eta_0}{\eta} = C^{n/3}, \]  

where \(\eta_0\) and \(\eta\) are the luminescence quantum efficiency of Eu\textsuperscript{2+} in the absence and presence of Mn\textsuperscript{2+}, respectively; the values of \(\eta_0/\eta\) can be approximately calculated by the ratio of related luminescence intensities (\(I_{S0}/I_S\)); \(C\) is the content of Mn\textsuperscript{2+}; \(n = 6, 8, 10\) correspond to dipole-dipole, dipole-quadrupole, and quadrupole-quadrupole interactions, respectively. The \(I_{S0}/I_S\) vs. \(C^{n/3}\) plots are further illustrated in Figs. 3(a) and 3(b), and the linear relation was observed only when \(n = 8\), implying that ET\textsubscript{Eu−Mn} is the dipole-quadrupole mechanism, which is similar to those previously investigated and observed in our group.\textsuperscript{3,6}

The critical distance (\(R_c\)) of ET\textsubscript{Eu−Mn} for the dipole-quadrupole mechanism can be calculated by the following simplified equation for dipole-quadrupole mechanism:\textsuperscript{3}

\[ R_c^6 = 0.63 \times 10^{28} f_d^2 \frac{Q_A}{f_d^2} \int F_d(E) F_A(E) dE, \]  

where \(Q_A\) is the absorption coefficient of Mn\textsuperscript{2+} that is equal to \(4.8 \times 10^{10} f_d\) given by Blasser;\textsuperscript{12} \(f_d = 10^{-7}\) and \(f_d = 10^{-10}\) are the oscillator strengths of the activator (Mn\textsuperscript{2+}) dipole and quadrupole electric transitions, respectively; \(\lambda_S\) (in Å) and \(E\) (in eV) are the emission wavelength and emission energy of Eu\textsuperscript{2+}; \(F_d(E)\) and \(F_A(E)\) express the spectral overlap between the normalized shapes of Eu\textsuperscript{2+} emission \(F_A(E)\) and Mn\textsuperscript{2+} excitation \(F_d(E)\), and it is estimated at about 1.79 eV\textsuperscript{−1}. Therefore, the \(R_c\) for ET\textsubscript{Eu−Mn} in CMSO:Eu,Mn was reckoned to be 11.97 Å, which is longer than 11.4 and 10.8 Å reported for SrZn\textsubscript{2}(PO\textsubscript{4})\textsubscript{2}:Eu, Mn (Ref. 6) and CaSi\textsubscript{2}Al\textsubscript{2}O\textsubscript{6}:Eu, Mn,\textsuperscript{5} respectively.

The diffuse reflectance spectra of selected samples doped with different amounts of Mn\textsuperscript{2+} and the pristine
Ca$_2$MgSi$_2$O$_7$ are depicted in Fig. 4. The Ca$_2$MgSi$_2$O$_7$ host shows an absorption edge only in the UV spectral region. However, the strong absorption in the near-UV to visible spectral region (370–450 nm) was clearly observed not only for Ca$_2$MgSi$_2$O$_7$:Eu$^{2+}$ but also for Eu$^{2+}$- and Mn$^{2+}$-codoped systems, and the results were found to be consistent with the PLE spectra shown in Fig. 2(a).

Figure 5 portrays the Commission International de l’Eclairage (CIE) chromaticity coordinates for CM-SO:Eu,Mn phosphors with various dopant concentrations. The chromaticity coordinates $(x, y)$ of (Ca$_{1-n}$Eu$_{m}$)$_2$Mg$_{1-n}$Mn$_n$Si$_2$O$_7$ vary from (0.36, 0.55) (point $G$) through (0.45, 0.44) and finally to (0.57, 0.36) (point $R$) corresponding to solely Eu$^{2+}$-doped, Eu$^{2+}$- and Mn$^{2+}$-coactivated, and solely Mn$^{2+}$-doped systems, respectively. As shown in Fig. 5, points on the line $GR$ represents the change of hue from yellow-green to orange-red and this variation is also summarized in Table I. We have observed that white light can be generated by exciting (Ca$_{1-n}$Eu$_{m}$)$_2$Mg$_{1-n}$Mn$_n$Si$_2$O$_7$ phosphors under 381 nm radiation source with chromaticity coordinates at (0.18, 0.00) (point $B$). Comparing the white light produced by our emission-tunable phosphors and violet-blue light source that from commercial YAG:Ce and blue LED chip, our system shows exceptionally flexible hues with increasing Mn$^{2+}$ content than those of the commodity because the approaching RGB primary area can be effectively established in our system. The above observations hint enormously promising application of CMO:Eu,Mn as a single-phased white-emitting phosphor under violet-blue irradiation.

In conclusion, the white light with varied hues and color temperature has been obtained by combination of wavelength-tunable yellowish green-to-orange red-emitting Ca$_2$MgSi$_2$O$_7$:Eu,Mn phosphors and the violet-blue (381–420 nm) radiation source. The energy transfer from Eu$^{2+}$ to Mn$^{2+}$ in Ca$_2$MgSi$_2$O$_7$:Eu,Mn phosphors has been demonstrated to be a resonant type via a dipole-quadrupole mechanism. Therefore, the Ca$_2$MgSi$_2$O$_7$:Eu,Mn phosphors can play an important role in a potential single-phased white-emitting phosphor for violet-blue emitting LEDs by utilizing the principle of energy transfer and properly designed activator contents.

The authors acknowledge the generous financial support from the National Science Council of Taiwan under Contract No. NSC95-2113-M-009-024-MY3 and helpful suggestions from Woan-Jen Yang of PRL, NCTU are also acknowledged.
