In this study, we demonstrated experimentally that formation of chains and islands of oxygen vacancies in hafnium sub-oxides (HfO\(_x\), \(x < 2\)) leads to percolation charge transport in such dielectrics. Basing on the model of Efros-Shklovskii percolation theory, good quantitative agreement between the experimental and theoretical data of current-voltage characteristics was achieved. Based on the percolation theory suggested model shows that hafnium sub-oxides consist of mixtures of metallic Hf nano-scale clusters of 1–2 nm distributed onto non-stoichiometric HfO\(_x\). It was shown that reported approach might describe low resistance state current-voltage characteristics of resistive memory elements based on HfO\(_x\). © 2014 AIP Publishing LLC. [http://dx.doi.org/10.1063/1.4905308]

Hafnium oxide (hafnia, HfO\(_2\)) and sub-oxides (HfO\(_x\), \(x < 2\)) play extremely important roles in modern microelectronics. Hafnia is used in modern MOSFETs as high-\(k\) gate dielectric with low leakage currents.1–4 Hafnium sub-oxides are the most promising materials to be used as active medium in resistive random access memory (RRAM),5,6 which are the most promising materials to be used as active media of Si/TaN/HfO\(_x\)/Ni. To fabricate these structures, we deposited the 8-nm-thick amorphous HfO\(_x\) on 100-nm-thick TaN films on Si wafers, using physical vapor deposition. A pure HfO\(_2\) target was bombarded by an electron beam, and HfO\(_2\) was deposited on the wafer. No post deposition annealing was applied to produce highly non-stoichiometric HfO\(_x\) films. Structural analysis showed that the resulting films were amorphous. All samples for transport measurements were equipped with round 50-nm-thick Ni gates with a radius of 70 \(\mu\)m.

Transport measurements were performed using a Hewlett Packard 4155B semiconductor parameter analyzer and an Agilent E4980A precision LCR meter. All measurement equipments were protected against short circuiting with the current through the sample limitation of 1 \(\mu\)A.

The most commonly used LRS description in RRAM structures consists of conductive filament (CF), approximately 1–10 nm in diameter.15–17 The CF forming is caused by charged ion movements due to temperate gradients and electric fields.17 It was supposed that CFs in Ni/HfO\(_2\)/Si RRAM structures consist of nickel, migrated from the metal electrode,16 but these assumptions were based on results of RRAM measurements in Ni/NiO/Ni-type structures (i.e., with NiO dielectric medium with Ni electrodes). However, CF has metallic temperature dependence of resistance

\[
(R - R_0) \propto (T - T_0)
\]

(here \(R_0\) is the CF resistance at temperature \(T_0\), with average resistivity in three order smaller than resistivity of pure Hf metal.15

Experimental current-voltage characteristics (\(I-V\)) in Si/TaN/HfO\(_2\)/Ni MIM structures at different temperatures are shown in Fig. 1 by colored characters. The measured current in LRS has strong exponential dependence on voltage and temperature. Expected current through non-stoichiometric HfO\(_2\) CF15 (dark cyan dotted line in Fig. 1) is close to experiment results, but expected values are large for temperatures of \(T = 25–50^\circ\)C, and lower than measured at \(T = 85^\circ\)C. The current grows exponentially with temperature growing, while following results from the literature, the current should decrease with the temperature increasing (1).

Therefore, we suppose that LRS conductivity is conditioned by the presence of a non-stoichiometric HfO\(_x\) islands in HfO\(_2\) matrix as HfO\(_x\) with \(y \leqslant 1.89\) splits into phases of Hf, HfO\(_{1.5}\), and HfO\(_2\).18 The overview on the structure of non-stoichiometric sub-oxides and sub-nitrides was developed for SiO\(_x\), SiN\(_x\), and SiO\(_x\)N\(_y\).19–22

A 2D structural image of non-stoichiometric HfO\textsubscript{x}, regarding the intermediate structural model,\textsuperscript{20} is presented in Fig. 2(a). According to this model, the CF in hafnium suboxide consists of a mixture of metallic hafnium nanoscale clusters (blue drops) and non-stoichiometric HfO\textsubscript{x} (green islands) distributed onto HfO\textsubscript{2} matrix (yellow area). Fig. 2(c) is an energy diagram of HfO\textsubscript{2} in the intermediate structural model. According to this plot, spatial fluctuations in the chemical composition of HfO\textsubscript{2} lead to local band gap width spatial fluctuations. The maximal fluctuation of the energy scale is equal to the HfO\textsubscript{2} band gap width of \(E_g = 5.6\) eV.\textsuperscript{23} The work function of metallic hafnium is 4.0 eV. The maximal fluctuation scale of the HfO\textsubscript{x} conduction band is 2.0 eV, which equals the electron barrier height of Hf/HfO\textsubscript{2} interface. The hole energy barrier of Hf/HfO\textsubscript{2} is 3.6 eV (Fig. 2(b)), which leads to the maximal fluctuation scale of the HfO\textsubscript{x} valence band of 3.6 eV.

The nanoscale fluctuations at the bottom of conduction band \(E_c\) and at the top of valence band \(E_v\) are close to those proposed in the model developed in Refs. 24 and 25, as shown in Fig. 2(d). The charge transport in such electron systems can be described according to percolation. This model assumes that excited electrons with energy higher than the flow level \(E^f\) are delocalized, and driving round a random potential, transfer the charge. The hole conductivity is realized through the excitation of electrons with energy \(E^h\) to the Fermi level. These excitations form hole-type quasiparticles, which transfer the charge. In other words, to be involved in transport processes, electrons and holes must overcome energy thresholds (\(W^{e,h}\) here, and \(W^{e} \neq W^{h}\), in general). The current-voltage characteristics are exponentials\textsuperscript{24}

\[
I(T) = I_0(T)\exp\left(\frac{(CeFa_0V_0)^{17.5}}{kT}\right),
\]

where \(I\) is the current, \(I_0\) is the preexponential factor, \(e\) is the electron charge, \(F\) is the electric field, \(a\) is the space scale of fluctuations, \(V_0\) is the amplitude of energy fluctuation, \(k\) is the Boltzmann constant, \(C\) is a numeric constant, and \(\nu\) is a critical index. The values of the constants were derived from Monte-Carlo simulations and evaluated at \(C \simeq 0.25\) (Ref. 24) and \(\nu = 0.9\).\textsuperscript{25} Percolation energy threshold \(W\) can be evaluated based on the temperature dependency of the preexponential factor

\[
I_0(T) \sim \exp\left(-\frac{W}{kT}\right).
\]

The solid colored lines in Fig. 1 indicate the results of LRS simulations regarding the percolation model, given in (2). Numeric fitting returns the value of combination as \(Ca_0V_0^{0.9} = 0.45\) nm . eV\textsuperscript{0.9}, which corresponds to \(V_0 = 1.9\) eV when \(a = 1\) nm and \(C = 0.25\). The slope of a fitting line in a \(\ln(I_0)-v_s-T^{-1}\) plate according to (3) corresponds to a percolation threshold of \(W \approx 1.0\) eV. Because \(W \leq V_0 \leq 2.0\) eV (for electrons), we can estimate the space size of nanoscale fluctuations as \(a \approx 1-2\) nm.

Previous experiments in charge transfer have demonstrated that hafnia conductivity is bipolar (or two-band):\textsuperscript{4,26–28} electrons are injected from a negatively shifted contact in the dielectric, and holes are injected from a positively shifted electrode in the dielectric. In our model, LRS conductivity can also be studied using electrons and holes. For the reason of simplicity, the current study was limited for considering monopolar electron conductivity.
The results demonstrate that charge transport in non-stoichiometric hafnium sub-oxides is described according to the percolation model in electron systems exhibiting potential nanoscale fluctuations. This approach can be applied to explain RRAM in GeO$_x$- and SiO$_x$-based structures.\textsuperscript{29,30}
