ABSTRACT

Recently, digital video broadcasting-handheld (DVB-H) and IP datacast over DVB-H (DVB-IPDC) have been developed to support broadcasting services. DVB-H is designed to support digital video broadcast for handheld devices, whereas DVB-IPDC can integrate with an IP-relay network to complement the data loss problem in DVB-H. Assuming that WiMAX networks are adopted to support DVB-IPDC, this paper points out two critical problems: group packet loss (GPL) and broadcast data handover (BDH). GPL occurs when there is a burst of retransmission requests for the same pieces of data with high spatial or temporal correlation. BDH happens when some devices that made the above requests handover to new serving cells. To solve these problems, we propose lazy wait and group acknowledgement schemes to alleviate duplicate requests by exploiting their spatial and temporal correlations. This not only reduces the requests submitted by neighboring devices in both space and time domains but also avoids handovering devices from sending duplicate requests in new cells. Through mathematical analysis, we show how to adaptively adjust the timers of lazy wait and group acknowledgement based on channel quality. Simulation results prove that our schemes can efficiently reduce retransmission requests and retransmission packets, thus alleviating congestion in the IP-relay network. 1. INTRODUCTION

Digital video broadcasting-handheld (DVB-H) [1,2] is developed from the successful DVB-T (terrestrial) system with special designs for handheld, battery-powered devices. DVB-H adopts a time-slicing mechanism to reduce the energy consumption of mobile devices (MDs). Because MDs are vulnerable to packet loss in a wireless environment [3,4], a feedback mechanism to request retransmissions is necessary. There are two possible solutions. One is to use the DVB-H return channel to request the lost packets. However, not only the return channel is quite small but also the DVB-H server can be easily overloaded [5]. The other solution is to adopt IP datacast over DVB-H (DVB-IPDC) [6–8], which relies on cooperating with a separate wireless network, such as an IP-relay wireless network, to allow MDs to submit requests and receive lost packets.

This paper supports DVB-IPDC by adopting broadband WiMAX networks [9,10] as an example to serve as the datacast channel. We consider MDs roaming inside the coverage of both DVB-H and WiMAX networks, as shown in Figure 1. The DVB-H server continuously broadcasts digital videos to MDs. When an MD detects any packet† loss, it requests a nearby WiMAX relay station (RS) for retransmission. Under this architecture, we point out two critical problems: group packet loss (GPL) and broadcast data handover (BDH). GPL occurs when there are burst of requests for retransmissions of the same pieces of data with high spatial or temporal correlation. Thus, some RSs may be seriously congested by incoming requests and outgoing retransmissions. On the other hand, BDH occurs when some MDs handover to neighboring RS cells

---

†In this paper, a “packet” means a DVB-H packet.
after submitting their requests. Thus, duplicate requests and retransmissions could further congest the WiMAX network.

To solve these problems, we should prevent MDs from sending duplicate requests and deliver lost packets effectively. In fact, many requests could exhibit spatial or temporal correlations. In the space domain, neighboring MDs may send similar requests because they are interfered by the same noise or obstacles. Moreover, the handover behavior of MDs may extend this spatial correlation to neighboring cells. In the time domain, some MDs may lose a sequence of packets because the interference sources often exist for a spell. If redundant requests and retransmissions can be merged, the network efficiency can be greatly improved.

This paper proposes a bulk recovery with lazy wait (BR-LW) scheme to deal with the GPL and BDH problems by exploiting the spatial and temporal correlations of retransmission requests. The idea is to adopt the lazy wait and group acknowledgement mechanisms. Specifically, when an MD detects any packet loss, it “lazily” waits a random period and only sends the request to its associated RS if needed. Then each RS accumulates the requests from its MDs and broadcasts a group acknowledgement $g_{ack}$ to its cell to announce the requests it has received. On receiving $g_{ack}$, each MD cancels those requests that appear in $g_{ack}$ but have not been sent out yet. Also, the RS packs its accumulated requests in bulk and sends it to the WiMAX base station (BS). The BS queries the DVB-H server for the lost packets and then sends these packets to MDs through the corresponding RSs.

In BR-LW, we adopt three special designs to reduce duplicate requests and improve network efficiency:

- With lazy wait, each MD can pack many small requests together and sends one bulk request to the RS. Thus, not only is the amount of message transmissions reduced but also network contention is alleviated. The waiting period should be adaptively adjusted based on the DVB-H channel condition. When the MD experiences a bad channel, a shorter period is adopted to quickly recover the lost packets; otherwise, a longer period is adopted to accumulate more requests.

- The group acknowledgement $g_{ack}$ not only confirms the receipt of requests by the RS but also prevents MDs from sending duplicate requests. The timing to send $g_{ack}$ should consider the spatial and temporal correlations of requests. When most requests exhibit high spatial or temporal correlation, $g_{ack}$ is sent immediately to avoid further duplication. Otherwise, the RS can defer $g_{ack}$ to collect more requests.

- The BS also takes advantage of the spatial and temporal correlations of retransmission requests to improve the transmission efficiency. In the space domain, we divide RSs into several multicast groups according to their positions, so that the BS can multicast the requested packets to adjacent RSs altogether to reduce the amount of transmissions. In the time domain, the BS proactively fetches correlated packets from the DVB-H server in advance to reduce the downloading latency.
Major contributions of this paper are threefold. First, we point out the new GPL and BDH problems under the DVB-IPDC environment. Second, we propose the lazy wait and group acknowledgement schemes to solve these problems by exploiting the spatial and temporal correlations of requests. Simulation results show that our schemes can significantly reduce the amounts of retransmission requests and retransmission packets, thereby alleviating network congestion. Third, with mathematical analysis, we discuss how to adaptively adjust the timers of lazy wait and $g_{ack}$ according to the channel conditions.

The rest of this paper is organized as follows. Section 2 gives the problem statements and surveys related work. Section 3 presents the BR-LW scheme, whereas Section 4 discusses how to determine its system parameters. Simulation results are shown in Section 5. Conclusions are drawn in Section 6.

2. PRELIMINARIES

2.1. Problem statements

We consider a DVB-H system with WiMAX networks as the datacast channel (refer to Figure 1). Each MD is equipped with a DVB-H data receiver and a WiMAX wireless interface. The WiMAX networks consist of multiple BSs connected to the DVB-H server through an IP-based network. Each BS supports multiple RSs. MDs continuously receive the DVB-H broadcast data and ask their associated RSs to retransmit the lost packets. Each packet has a deadline, and a packet missing its deadline will be dropped. We assume that each MD maintains a small playback buffer and that there is an upper-layer protocol to manage the buffer to guarantee some video quality of service (QoS) requirements, such as jitter and peak signal-to-noise ratio (PSNR). Therefore, in this paper, we only focus on the retransmission of lost packets to avoid missing their deadlines.

For each BS, it collects the requests from its RSs, packs and forwards these requests to the DVB-H server, and then sends the requested packets to MDs through the corresponding RSs. In the above architecture, the GPL problem occurs when MDs send duplicate requests for the same packets (i.e., the requests exhibit spatial correlation) or multiple requests for consecutive packets (i.e., the requests exhibit temporal correlation). The BDH problem occurs when an MD sends its requests to an RS, handovers to another RS, and then resends the same requests to this new associated RS again. Our goal is to reduce the above redundancy to improve retransmission efficiency and avoid potential congestion in the WiMAX networks.

2.2. Related work

Digital video broadcasting-handheld is developed from the DVB-T system, which relies on uni-directional broadcast. Prior studies thus focus on integrating DVB-T with other wireless networks to provide two-way communications. For example, Reference [11] suggests adopting GSM networks for this purpose. In Reference [12], a GPRS network is adopted to support near-media-on-demand service such as MP3 delivery. References [13,14] address the integration of 3G, WLAN, and DVB-T, networks, where the objective is to manage the composite network resources. A seamless, cross-layer interworking scheme between DVB-T and IEEE 802.11 WLANs is proposed in Reference [15] to provide interactive mobile TV services, where a gateway is deployed in each access network to conduct media adaptations. Similarly, References [16] proposes a testbed for mobile interactive television, where DVB-H streams are accessed through WiFi networks. In References [17], the concept of mobile social television is proposed, where the DVB-H content is shared among mobile users through peer-to-peer interactivity. Automatic configuration of an IP-based interworking model among WLAN, 3G, and DVB-H is addressed in References [18].

Following the DVB-IPDC architecture, several research efforts consider recovering DVB-H data through an IP-relay wireless network. Reference [19] suggests multicasting a DVB-H stream to multiple receivers through a WiFi access point. This work relies on maintaining multicast group membership to avoid carrier sense multiple access with collision avoidance contention; it differs from our work in that we use the datacast channel only for retransmissions. The study of Gomez-Barquero and Bria [20] adopts a cellular network to transmit repair data for the receivers temporarily affected by noise, interference, or fading. Similarly, Reference [21] integrates DVB-H with a 3G network to transmit additional parity data for the recovery purpose. Reference [22] proposes an application-layer forward error correction scheme and a multiburst coding scheme to deliver DVB-H data to improve transmission robustness. However, none of the above work addresses the GPL and BDH problems. References [23,24] propose a content delivery protocol (CDP) for the DVB-IPDC architecture to recover lost or corrupted packets, and Reference [25] evaluates the cost of CDP’s repair mechanism. Note that CDP relies on a point-to-point mechanism, whereas ours adopts a more efficient point-to-multipoint mechanism. In Reference [26], MDs are organized as an ad hoc network, and each MD encountering packet loss will query the lost packets from other MDs. Reference [27] proposes a recovery mechanism based on a peer-to-peer basis connecting Mobile TV clients via Universal Mobile Telecommunications System to recover packets that have been lost during the Mobile TV DVB-H transmission. Different from References [26,27], our work follows the DVB-IPDC architecture to retransmit through an infrastructured network.

3. THE BULK RECOVERY WITH LAZY WAIT SCHEME

In this section, we describe our BR-LW scheme. How to adaptively adjust its system parameters will be discussed.
in Section 4. Table I summarizes our notations. Figure 2 illustrates the flowchart of BR-LW. We assume that each MD has a small buffer to store the received DVB-H packets before playback, so an MD can tolerate a reasonable delay $d_i$ for each packet $p_i$. Our goal is to reduce the amount of message transmissions between MDs and RSs and that between RSs and BSs to preserve wireless bandwidth and avoid network congestion. In the following sections, we present the operations conducted by MDs, RSs, and BSs.

### 3.1. Operations of machine devices

Each MD continuously receives the packets sent from the DVB-H server and maintains a table $T_{MD}$ to record the information of the lost packets. Specifically, for each lost packet $p_i$, the MD inserts an entry $(p_i, d_i, t^L_i)$ into its $T_{MD}$, where $d_i$ is the deadline and $t^L_i$ is the lazy-wait timer of packet $p_i$. Initially, the entry $(p_i, d_i, t^L_i)$ is set as “unqueried.” The value of timer $t^L_i$ is randomly selected from $(0, t_{lazy}]$, where $t_{lazy}$ is a system parameter to be selected according to the current DVB-H channel condition. Intuitively, when the MD experiences a bad channel, a smaller $t_{lazy}$ is set to enforce the MD to quickly react to packet loss; otherwise, a larger $t_{lazy}$ is set to allow the MD to accumulate more requests. (We will discuss how to adaptively adjust $t_{lazy}$ in Section 4.1.) Note that the order that these lazy-wait timers expired is not necessarily the same as the order that the corresponding packets were lost. Figure 2 gives an example. Although packet $p_1$ is lost earlier than packet $p_j$, timer $t^L_1$ expires later than timer $t^L_j$.

When any lazy-wait timer expires, the MD will send to its associated RS a recovery request $RREQ(d_i, p_1, \cdots, p_k)$ containing the earliest packet deadline $d_i$ and the indices of all lost packets $p_1, \cdots, p_k$ whose entries are “unqueried” in its $T_{MD}$. We assume that the transmissions of RREQs are more reliable (guaranteed by an acknowledgement mechanism). Then the MD marks all entries in its $T_{MD}$ as “queried” and cancels all active lazy-wait timers. For example, in Figure 2, because timer $t^L_1$ expires first, MD 1 will send an $RREQ$ and cancel timers $t^L_1$ and $t^L_j$.

Each MD continuously repeats the above actions (i.e., inserts entries for lost packets into $T_{MD}$ and marks entries as “queried” by sending RREQs). However, when the MD receives a group acknowledgement $g_{ack}$ from its associated RS while its $T_{MD}$ is non-empty, it will mark those entries in its $T_{MD}$ that have the same packet indices in $g_{ack}$ as “queried” and then cancel the corresponding lazy-wait timers. Figure 2 shows an example. Supposing that MD 1 receives $g_{ack}$ that contains the packet indices $p_x$ and $p_y$. MD 1 will mark the entries $(p_x, d_x, t^L_x)$ and $(p_y, d_y, t^L_y)$ as “queried” and cancel the active timers $t^L_x$ and $t^L_y$. When either deadline $d_i$ expires or the MD receives packet $p_i$, the entry $(p_i, d_i, t^L_i)$ is removed from $T_{MD}$.

To deal with the BDH problem, when an MD handovers to a new RS cell, two cases will be considered:

1. If all entries of the MD’s $T_{MD}$ are “unqueried,” which means that there are no pending RREQs in its old RS, this handovering MD behaves the same as a non-handovering MD.
2. If there are some entries marked as “queried” in $T_{MD}$, which means that the handovering MD did not receive the requested packets from the old RS, the MD will set all entries in its $T_{MD}$ as “unqueried” and initialize a lazy-wait timer $t^L_{HO}$. The value of $t^L_{HO}$ is also randomly selected from $(0, t_{lazy})$. This lazy-wait timer is not associated with any packet. Its purpose is to ensure that this handovering MD still has a chance to send a RREQ to let the new RS know its (previously) lost packets if the MD does not experience any packet loss after handovering to the new RS cell.

---

---

1That is, the MD sends RREQs to the RS, but the RS has not returned the requested packets yet.
When any of the lazy-wait timers expires, this handovering MD will send a RREQ to the new RS and cancel all active lazy-wait timers (including $t_{LHO}$).

The above lazy wait design has three advantages. First, we can prevent MDs from sending a large number of small RREQs. Instead, an MD can combine all requests together and send a bulk RREQ. Thus, not only the overhead of packet headers is reduced but also the network contention is also alleviated. Second, the random waiting periods help differentiate RREQs’ transmission time and thus reduce potential packet collisions. Third, by deferring RREQs, the probability to receive $g_{ack}$ before sending RREQs is increased, thus avoiding MDs from sending duplicate requests to the RS. Because a handovering MD will also conduct lazy wait in the new RS cell, some of its duplicate requests could be eliminated if packet loss in both new and old RS cells exhibit spatial correlation.

### 3.2. Operations of relay stations

Each RS should keep the RREQs received from its associated MDs in a table $T_{RS}$. Each entry $(p_i, n_i)$ in $T_{RS}$ contains the index of a lost packet $p_i$ and the number $n_i$ of MDs that request packet $p_i$. Every time $T_{RS}$ changes from empty to non-empty, a timer $t_{g_{ack}}$ is initiated to determine the deadline to broadcast $g_{ack}$. The expiration of $t_{g_{ack}}$ should be earlier than the earliest packet deadline in each received RREQ. For example, in Figure 2, $t_{g_{ack}}$ should expire earlier than the earliest packet deadline $d_i$.

In addition, the RS should check two parameters $c_{num}$ and $c_{var}$ whenever the content of its $T_{RS}$ changes, where $c_{Num}$ is the total number of entries in $T_{RS}$ and $c_{var}$ is the coefficient of variation of all $n_i$’s in $T_{RS}$ that is defined as the ratio of the standard deviation of all $n_i$’s to their mean. The RS will broadcast a $g_{ack}$ immediately to its associated MDs if any of the following conditions is true:

1. $c_{num} \geq \delta_{num}$: Because the RS will clear $c_{num}$ and $T_{RS}$ whenever it sends out $g_{ack}$ (this will be discussed later), the functionality of $T_{RS}$ can be viewed as a “sliding window” to record which packets are lost among a small set of packets broadcasted from the DVB-H server in each round. Therefore, when the number of entries in $T_{RS}$ (i.e., $c_{num}$) exceeds a threshold $\delta_{num}$, there is a high probability that consecutive or semi-consecutive packets are lost. In other words, these RREQs could exhibit temporal correlation.
(2) \( c_{\text{var}} \geq \delta_{\text{var}} \): When the coefficient of variation \( c_{\text{var}} \) exceeds a threshold \( \delta_{\text{var}} \), it means that some of the packets may be lost by a large number of MDs. In this case, these RREQs could exhibit spatial correlation.

(3) \( \sum_{(p, n) \in T_{\text{MP}}} n_i \geq \zeta \): When both \( c_{\text{num}} < \delta_{\text{num}} \) and \( c_{\text{var}} < \delta_{\text{var}} \), but the RS has collected a sufficient number \( \zeta \) of RREQs, this also implies some sort of spatial correlation of received RREQs.

(4) Timer \( t_{g_{\text{ack}}} \) expires: If none of the above three conditions are met, it means that most RREQs are not correlated. Thus, the RS defers \( g_{\text{ack}} \) until timer \( t_{g_{\text{ack}}} \) expires to collect more RREQs.

Parameters \( \delta_{\text{num}}, \delta_{\text{var}}, \) and \( \zeta \) are thresholds to determine how quickly the RS should broadcast \( g_{\text{ack}} \) before timer \( t_{g_{\text{ack}}} \) expires. The threshold \( \zeta \) can be calculated by past statistics. We will discuss how to adaptively adjust \( \delta_{\text{num}} \) and \( \delta_{\text{var}} \) in Section 4. If any condition above is met, the RS broadcasts a \( g_{\text{ack}} \) containing all packet indices in its \( T_{\text{RS}} \).

As to the content of the \( g_{\text{ack}} \), our design will try to exploit both spatial and temporal correlations of RREQs to inhibit potential future RREQs. There are two rules.

(1) In the space domain, \( g_{\text{ack}} \) will contain all packet indices that have received so far. This prevents nearby MDs from sending duplicate requests. Specifically, when an MD sends the request of a lost packet \( p_l \) to the RS, other neighboring MDs that also lose packet \( p_l \) but have not sent their requests yet will cancel their submissions after receiving \( g_{\text{ack}} \). In Figure 2, suppose that MD2’s RREQ contains packet indices \( p_x \) and \( p_y \). If the \( g_{\text{ack}} \) from the RS also contains \( p_x \) and \( p_y \), MD1 will remove \((p_x, dx, t_x^i)\) and \((p_y, dy, t_y^i)\) from its \( T_{\text{MD}} \).

(2) In the time domain, the RS tries to predict future lost packets. Specifically, if it finds a sequence of packet indices \( p_n \rightarrow p_{n+1} \rightarrow p_{n+2} \rightarrow \cdots \rightarrow p_{n+\alpha} \) in its \( T_{\text{RS}} \), the \( g_{\text{ack}} \) will include \( \alpha \) more packet indices \( p_n, p_{n+1}, p_{n+2}, \cdots, p_{n+\alpha} \) so as to exploit temporal correlation of RREQs. Here, \( \alpha \) and \( \beta \) are system parameters.

After sending \( g_{\text{ack}} \), the RS cancels timer \( t_{g_{\text{ack}}} \) if it has not expired yet, resets its \( c_{\text{num}} \) and \( c_{\text{var}} \) to zeros, sends a bulk request containing all of the packet indices in \( g_{\text{ack}} \) to the BS, and clears its \( T_{\text{RS}} \). Note that to reduce the overhead of packet headers and alleviate network contention, each RS also packs small requests together and then sends one bulk request to the BS.

For the BDH problem, we suggest dividing RSs into multiple multicast groups according to their relative positions in deployment, where adjacent RSs will be grouped together [28,29]. Because MDs usually handover to adjacent RSs, this behavior could make the received RREQs exhibit spatial correlation in each multicast group of RSs. Therefore, the BS can take advantage of multicast to alleviate BDH by simultaneously sending the requested packets to the RSs in the same multicast group. This issue will be further discussed later.

After obtaining the packets from the BS, the RS will send these packets to all its MDs through broadcasting. Using broadcasting has two advantages over using uncasting. First, the RS does not need to record which packets are lost by which MD, thus reducing storage and maintenance costs (especially when there are many handovering MDs). Second, the RS can significantly alleviate the amount of transmissions if most MDs lose similar packets. In addition, even when there are many handovering MDs, broadcasting can help reduce the cost of sending orphan packets (i.e., those packets no longer requested by any MD).

### 3.3. Operations of base stations

Recall that RSs will be divided into multiple multicast groups according to their positions. For each multicast group of RSs, the BS will collect (and pack) their requests and send a bulk request to the DVB-H server to ask for retransmissions of lost packets. Then the BS will multicast the requested packets to the member RSs in the multicast group. The above multicast takes advantage of spatial correlation of requests because MDs in some adjacent RS cells may lose similar packets. Besides, the handovering behavior of MDs extends this spatial correlation to neighboring RS cells. To take advantage of temporal correlation of requests, the BS can prefetch a small number of future correlated packets from the DVB-H server. In this way, the downloading latency can be reduced.

Note that the goal of this paper is to reduce redundant requests to avoid bandwidth waste and network congestion. How to guarantee video QoS requirements, such as jitter and PSNR, is out of the scope of this paper. Therefore, BR-LW adopts \( c_{\text{num}} \) and \( c_{\text{var}} \) to help RSs decide when to broadcast \( g_{\text{ack}} \) to alleviate redundant requests. For the delay concern, because packets have deadlines and MDs will drop those out-of-date packets, we consider a packet with no delay if the packet can be received by the MD before passing its deadline. Therefore, BR-LW makes MDs to notify the RS of packet deadlines so that these lost packets can be sent to MDs before they become out of date.

### 4. Determining System Parameters of Bulk Recovery with Lazy Wait

In this section, we discuss how to adaptively adjust the system parameters of BR-LW according to the network situation.

#### 4.1. Adjustment of lazy-wait timer \( t_{\text{lazy}} \)

The system parameter \( t_{\text{lazy}} \) determines how long an MD waits to send its RREQ after it incurs any packet loss. Intuitively, a shorter length of \( t_{\text{lazy}} \) is adopted if the MD incurs a bad DVB-H channel. In this case, because the MD is
expected to lose a large number of packets, the MD has to send its RREQ immediately to recover the lost packets. Otherwise, a longer length of $t_{\text{lazy}}$ is adopted to make the MD accumulate more requests into its RREQ. Therefore, we adjust the length of $t_{\text{lazy}}$ in a binary exponential manner as follows:

$$t_{\text{lazy}} = (d_i - t_{\text{current}}) \times 2^{-\mu_E} \quad (1)$$

where $t_{\text{current}}$ is the current time and $\mu_E$ is the expected number of successive lost packets by the MD.

To calculate $\mu_E$, we adopt a four-state aggregated Markov process (AMP), which can approximate the behavior of a DVB-H channel (even when the MD is moving) [30]. AMP considers a finite-state channel error model, where the states are divided into two groups $S_C$ and $S_E$ that correspond to the correct and erroneous reception of packets, respectively. Each group is associated with an output symbol that emits at each state transition and ends at the given group. In particular, let $X = \{X_0, X_1, \ldots\}$ be a time-homogenous Markov chain with a four-state space $S = \{1, 2, 3, 4\}$. We can divide $S$ into two groups, $S_C : \{1, 2\}$ and $S_E : \{3, 4\}$. Let $\Phi : S \to \{c, e\}$ be an emission function, where $\Phi(i) = c$ if $i \in S_C$ and $\Phi(i) = e$ if $i \in S_E$. If we denote the output process of $X$ as $Y = \{Y_0, Y_1, \ldots\}$ with state space $(c, e)$, then $Y$ is an AMP.

The transition probability matrix of $X$ is defined as

$$M_X = [P_{ij}]_{4 \times 4} = \begin{bmatrix} P_{11} & P_{12} & P_{13} & P_{14} \\ (1 - P_{11})P_{21} & (1 - P_{12})P_{22} & (1 - P_{13})P_{23} & (1 - P_{14})P_{24} \\ (1 - P_{13})P_{31} & (1 - P_{12})P_{32} & P_{33} & (1 - P_{14})P_{34} \\ (1 - P_{14})P_{41} & (1 - P_{14})P_{42} & (1 - P_{14})P_{43} & P_{44} \end{bmatrix}$$

where $P_{ij}$ is the transition probability from state $i$ to state $j$, $1 \leq i, j \leq 4$; the condition $0 \leq P_{ij} \leq 1$ holds for $i = 1, 2, 3, 4$; and $P_{ii}$, for $i = 1, 2, 3, 4$, are the weights such that $\omega_1 + \omega_2 = 1$ and $\omega_3 + \omega_4 = 1$.

Let $\pi(n) = \begin{bmatrix} \pi_1(n) \\ \pi_2(n) \\ \pi_3(n) \\ \pi_4(n) \end{bmatrix}$ be the vector of state probability distribution, where each $\pi_i(n)$, $i = 1, 2, 3, 4$, is the unconditional probability of being in state $i$ at time $n$. Let $\pi = \lim_{n \to \infty} \pi(n) = [\pi_1 \pi_2 \pi_3 \pi_4]$. If the limit exists, $\pi$ is a stationary distribution. Thus, we can calculate $\pi$ by $\pi \cdot M_X = \pi$ and $\pi \cdot 1 = 1$. Therefore, we can obtain that

$$\pi_i = \frac{\omega_i}{(1 - P_{ii}) \sum_{j=1}^{4} \frac{\omega_j}{1 - P_{ij}}} \quad \text{for } i = 1, 2, 3, 4$$

With $\pi$, we can calculate the probability that an MD incurs erroneous reception of packets by

$$\text{Prob}(Y = e) = \sum_{i \in S_E} \pi_i = \pi_3 + \pi_4 = \frac{\omega_3}{(1 - P_{33}) \sum_{j=1}^{4} \frac{\omega_j}{1 - P_{ij}}} + \frac{1 - \omega_3}{(1 - P_{44}) \sum_{j=1}^{4} \frac{\omega_j}{1 - P_{ij}}} \quad (2)$$

On the other hand, the value of $\text{Prob}(Y = e)$ can be measured by the average packet error rate of the MD during a fixed observation window. Therefore, the moving behavior of the MD is also considered because it will impose an effect on the received signal strength. By assigning weights $\omega_1$, $\omega_2$, $\omega_3$, and $\omega_4$, we can adopt the Levenberg–Marquardt algorithm [31] to calculate the variables $\rho_1$, $\rho_2$, $\rho_3$, and $\rho_4$ in Equation (2).

Now, let $D_E$ be the discrete random variable of the dwell time in state group $S_E$. The probability mass function of $D_E$ is defined by [30]

$$P_{D}(n) = \text{Prob}(D_E = n) = \text{Prob}(X_{j+1} \in S_E, \ldots, X_{j+n} \in S_E, X_{j+n+1} \in S_C | X_j \in S_C, X_{j+1} \in S_E) = \sum_{i=3}^{4} \omega_i \rho_i^{n-1} (1 - \rho_i), \quad \text{for } n = 1, 2, \ldots$$

Then the probability-generating function of $D_E$ is calculated by

$$G_D(z) = \sum_{n=1}^{\infty} P_{D}(n) z^n = \sum_{n=1}^{\infty} \left( \sum_{i=1}^{n} \omega_i \rho_i^{n-1} (1 - \rho_i) \right) z^n$$

$$= \sum_{n=1}^{\infty} \left( \sum_{i=3}^{4} \omega_i (1 - \rho_i) \rho_i z^{n-1} \right) \sum_{n=1}^{\infty} (\rho_i z)^n$$

$$= \sum_{i=3}^{4} \omega_i (1 - \rho_i) \rho_i z \sum_{n=1}^{\infty} (\rho_i z)^n$$

$$= \sum_{i=3}^{4} \omega_i (1 - \rho_i) \rho_i z \frac{\rho_i z}{1 - \rho_i z}$$

(3)

Let us define $f_i(z) = \frac{\rho_i z}{1 - \rho_i z}$. Then Equation (3) is written as

$$G_D(z) = \sum_{i=3}^{4} \omega_i (1 - \rho_i) \rho_i z \cdot f_i(z)$$

W.-H. Yang et al. 
Request control scheme for data recovery in DVB-IPDC systems

DOI: 10.1002/wcm
The kth derivative of \( f_i(z) \) is calculated by

\[
 f_i^{(k)}(z) = \frac{d^{k-1}}{dz^{k-1}} (f_i'(z))
 = \frac{d^{k-1}}{dz^{k-1}} (\rho_i (1 - \rho_i z) - \rho_i z (1 - \rho_i z))
 = \rho_i \cdot \frac{d^{k-1}}{dz^{k-1}} \left( \frac{1}{1 - \rho_i z} \right)
 = \frac{k! \rho_i^k}{(1 - \rho_i z)^{k+1}}
\]

Therefore, the kth derivative of \( G_D(z) \) is calculated by

\[
 G_D^{(k)}(z) = \sum_{i=3}^{4} k! \rho_i^{k-1} \omega_i (1 - \rho_i z)^{k+1}, \quad \text{for } k = 1, 2, \ldots
\]

By Equation (4), we can calculate the expectation of \( D_E \) as

\[
 \mu_E = G_D^{(1)}(1) = \frac{\omega_3}{1 - \rho_3} + \frac{1 - \omega_3}{1 - \rho_4}
\]

By substituting Equation (5) into Equation (1), we can obtain \( t_{lazy} \).

### 4.2. Adjustment of threshold \( \delta_{num} \)

The threshold \( \delta_{num} \) determines how quickly the RS will broadcast \( g_{ack} \). When \( c_{num} \geq \delta_{num} \), the RS sends a \( g_{ack} \) because the received RREQs may exhibit temporal correlation. Let \( \mathcal{R} = \{p_1, p_2, \ldots, p_{|\mathcal{R}|}\} \) be the set of the lost packets requested by RREQs that the RS collects during the \( t_{g_{ack}} \) period. The size of \( \mathcal{R} \) is

\[
 |\mathcal{R}| \leq \gamma \times e_{MD} \times t_{g_{ack}}
\]

where \( \gamma \) is the packet transmission rate of the DVB-H server and \( e_{MD} \) is the average packet error rate of an MD. Then we adopt the Zipf’s law [32] to calculate \( \delta_{num} \). According to the Zipf’s law, many types of data studied in the physical and social sciences such as on-demand broadcasting and video-on-demand services [33] can be approximated by Zipfian distributions. Thus, we model the arrival of RREQs by a Zipfian distribution. Besides, because of the lazy wait scheme, we assume that a continuous or near-continuous sequence of packet indices are put together in a single RREQ if the packet loss exhibits temporal correlation.

Suppose that the packets in \( \mathcal{R} \) are ranked *decreasingly* by the number of RREQs that query them. The Zipf’s law predicts that out of these \( |\mathcal{R}| \) packets, the frequency of a packet with rank \( k \) that appears in RREQs is

\[
 f(p_k) = \frac{1}{k^\theta}
 \]

where \( \theta \) is an exponent characterizing the Zipfian distribution. For instance, suppose that \( N_R = 5 \) and \( \theta = 0.6 \), the frequencies of packets \( p_1, p_2, p_3, p_4, \) and \( p_5 \) appearing in RREQs are 0.33, 0.22, 0.17, 0.15, and 0.13, respectively. In other words, about 33%, 22%, 17%, 15%, and 13% RREQs request packets \( p_1, p_2, p_3, p_4, \) and \( p_5 \), respectively. Therefore, we calculate \( \delta_{num} \) by

\[
 \delta_{num} = \sum_{i=1}^{N_R} f(p_i) \geq F_{th}
\]

where \( F_{th} \) is the expected cumulative frequency of the first \( \delta_{num} \) packets that most frequently appear in RREQs. Clearly, we have \( F_{th} > 0.5 \) (i.e., the first \( \delta_{num} \) packets are requested by more than half of all RREQs). For instance, we can set \( F_{th} = 0.7 \) and thus calculate \( \delta_{num} = 3 \) in the previous example. In this case, because the first three packets are requested by at least 70% RREQs, the RS can broadcast \( g_{ack} \) without waiting the remaining 30% RREQs.

### 4.3. Adjustment of threshold \( \delta_{var} \)

The threshold \( \delta_{var} \) also determines how quickly the RS will broadcast \( g_{ack} \). When \( c_{var} \geq \delta_{var} \), the RS sends a \( g_{ack} \) because the received RREQs may exhibit spatial correlation.

Let \( \varepsilon_1, \varepsilon_2, \ldots, \varepsilon_{|\mathcal{R}|} \) be the minimum values of \( n_1, n_2, \ldots, \) and \( n_{N_R} \), respectively, that trigger the RS to broadcast a \( g_{ack} \). When \( \varepsilon_i > 0 \) for all \( i = 1 \ldots N_R \). In other words, if \( n_i \geq \varepsilon_i \) for any \( i = 1 \ldots N_R \), the RS sends a \( g_{ack} \). Then \( \delta_{var} \) is calculated by the coefficient of variation of all \( \varepsilon_i \), \( i = 1 \ldots N_R \):

\[
 \delta_{var} = \sqrt{\frac{1}{N_R} \sum_{i=1}^{N_R} (\varepsilon_i - \varepsilon_{avg})^2} / \varepsilon_{avg}
\]

where \( \varepsilon_{avg} = (1/N_R) \sum_{i=1}^{N_R} \varepsilon_i \). Note that the sum of all \( \varepsilon_i, i = 1 \ldots N_R \), is smaller than \( \zeta \) (otherwise, by case 3 in Section 3.2, the RS sends a \( g_{ack} \) because of \( \sum_{i=1}^{N_R} n_i \geq \zeta \)). Thus, we have

\[
 \sum_{i=1}^{N_R} \varepsilon_i \leq \sum_{i=1}^{N_R} n_i < \zeta
\]

The values of \( \varepsilon_1, \varepsilon_2, \ldots, \varepsilon_{|\mathcal{R}|} \) can be calculated by an optimization problem whose objective is to minimize the total communication cost between the RS and its MDs. In particular, let \( \Theta(\zeta) \) be the number of messages exchanged between the RS and its MDs during the \( t_{g_{ack}} \) period, under the constraint in Equation (7). Therefore, we have

\[
 \Theta(\zeta) = N_{\text{RREQ}} + N_{\text{g_{ack}}}
\]

where \( N_{\text{RREQ}} \) is the number of RREQs sent by MDs and \( N_{\text{g_{ack}}} \) is the number of \( g_{ack} \) sent by the RS. Because the
RS sends only one \( g_{\text{ack}} \) during the \( t_{\text{ack}} \) period, we have \( N_{g_{\text{ack}}} = 1 \). Thus, the above equation is written as

\[
\Theta(\xi) = N_{\text{RREQ}} + 1 \tag{8}
\]

Our goal is to find the values of \( \varepsilon_1, \varepsilon_2, \ldots, \varepsilon_{NR} \) such that \( \Theta(\xi) \) is minimized.

Because \( \sum_{i=1}^{NR} n_i \geq \xi \) will trigger the RS to send a \( g_{\text{ack}} \), the maximum number of RREQs received by the RS before sending \( g_{\text{ack}} \) is \( \xi \). Therefore, before the condition \( c_{\text{var}} \geq \delta_{\text{var}} \) is satisfied, the expectation of \( N_{\text{RREQ}} \)

\[
E[N_{\text{RREQ}}] = \xi \times \text{Prob}(\text{no } g_{\text{ack}} \text{ is sent because of } c_{\text{var}} < \delta_{\text{var}}) \\
= \xi \times \text{Prob}(\text{no } g_{\text{ack}} \text{ is sent because of } \sum_{i=1}^{NR} n_i < \xi) \\
= \xi \times \text{Prob}(n_i < \varepsilon_i, \forall p_i \in \mathcal{R}) \times \text{Prob}(\sum_{i=1}^{NR} n_i < \xi) \\
= \xi \times \text{Prob}(\sum_{i=1}^{NR} n_i < \xi) \\
(9)
\]

We assume that each MD sends its RREQs independently with other MDs. By Equation (7), we obtain that

\[
\text{Prob}(n_i < \varepsilon_i, \forall p_i \in \mathcal{R}) \times \text{Prob}(\sum_{i=1}^{NR} n_i < \xi) \\
= \prod_{i=1}^{NR} \text{Prob}(n_i < \varepsilon_i) \times \text{Prob}(\sum_{i=1}^{NR} n_i < \xi) \\
= \prod_{i=1}^{NR} \text{Prob}(n_i < \varepsilon_i) \times \text{Prob}(\sum_{i=1}^{NR} n_i < \xi) \tag{10}
\]

By substituting Equation (10) into Equation (9), we have

\[
E[N_{\text{RREQ}}] = \xi \times \prod_{i=1}^{NR} \text{Prob}(n_i < \varepsilon_i) \tag{11}
\]

Thus, by Equation (11), Equation (8) is written as

\[
\Theta(\xi) = \xi \times \prod_{i=1}^{NR} \text{Prob}(n_i < \varepsilon_i) + 1 \tag{12}
\]

Because we have \( \varepsilon_i > 0 \) for each \( i = 1 \ldots NR \), we can obtain that \( \text{Prob}(n_i < \varepsilon_i) > 0 \). Besides, because \( \xi \) is a given constant, the only way to minimize \( \Theta(\xi) \) in Equation (12) is to minimize the value of \( \text{Prob}(n_i < \varepsilon_i) \) for each \( i = 1 \ldots NR \).

Recall that each \( n_i, i = 1 \ldots NR \), is the number of RREQs received by the RS. Thus, a combination of all \( n_i \)'s reflects the statistical quantity of RREQs that should follow some distribution (e.g., Zipfian distribution). Based on the definition, \( \varepsilon_i \) is the minimum value of \( n_i, i = 1 \ldots NR \), that triggers the RS to broadcast a \( g_{\text{ack}} \). Thus, the combination of all \( \varepsilon_i \)'s also follows the same distribution. Therefore, the value of \( \text{Prob}(n_i < \varepsilon_i) \) is expected to increase when \( n_i \) is close to \( \varepsilon_i \) for each \( i = 1 \ldots NR \). Based on the above observation, we define a distance function of \( n_i \) and \( \varepsilon_i \) as follows:

\[
H(n_i, \varepsilon_i) = \begin{cases} 
\max(n_i, \varepsilon_i) & \text{if } n_i < \varepsilon_i \\
1 & \text{otherwise}
\end{cases}
\]

When \( n_i < \varepsilon_i \), we have \( H(n_i, \varepsilon_i) > 1 \), and its value decreases when \( n_i \) is more close to \( \varepsilon_i \). On the other hand, when \( n_i \geq \varepsilon_i \), we define the value of \( H(n_i, \varepsilon_i) \) to be one.

By transforming the probability \( \text{Prob}(n_i < \varepsilon_i) \) to the distance function \( H(n_i, \varepsilon_i) \), our objective (to minimize \( \Theta(\xi) \) in Equation (12)) becomes

\[
\min_{i=1}^{NR} \prod_{i=1}^{NR} H(n_i, \varepsilon_i) \tag{13}
\]

By taking logarithm in Equation (13), we calculate the optimal values of \( \varepsilon_1, \varepsilon_2, \ldots, \varepsilon_{NR} \) to minimize \( \Theta(\xi) \) by the following optimization equations:

\[
\min \sum_{i=1}^{NR} \log H(n_i, \varepsilon_i) \\
\text{subject to } n_i > 0 \text{ for } i = 1 \ldots NR \\
\varepsilon_i > 0 \text{ for } i = 1 \ldots NR \\
0 \leq 0 < \sum_{i=1}^{NR} \varepsilon_i \leq \xi \tag{14}
\]

We can use the Karush–Kuhn–Tucker (KKT) algorithm [34] to solve Equation (14). Then by applying the values of all \( \varepsilon_i \)'s, \( i = 1 \ldots NR \), into Equation (6), we can calculate \( \delta_{\text{var}} \).

5. PERFORMANCE EVALUATION

In this section, we verify the effectiveness of BR-LW by simulations. In our simulations, there is one BS supporting four RSs, as shown in Figure 1. These four RSs belong to the same multicast group, and each RS serves ten MDs initially. We measure the amounts of RREQ submissions from the MDs and packet retransmissions from the RS under different distributions of DVB-H packet loss \( F \) and correlation feature of RREQs \( L \). The two distributions \( F \) and \( L \)
are normal distributions and independent with each other. For distribution $\mathcal{F}$, we consider three scenarios:

- **Left skew:** The peak of $\mathcal{F}$ appears in the left-hand side.
  \[ \mathcal{F} \left( X_{\mathcal{F}} = 0 \sim T, \mu_{\mathcal{F}} = \frac{1}{4} T, \sigma_{\mathcal{F}} = \frac{1}{2} T \right) \]
- **Balanced:** The peak of $\mathcal{F}$ appears in the middle.
  \[ \mathcal{F} \left( X_{\mathcal{F}} = 0 \sim T, \mu_{\mathcal{F}} = \frac{1}{4} T, \sigma_{\mathcal{F}} = \frac{1}{2} T \right) \]
- **Right skew:** The peak of $\mathcal{F}$ appears in the right-hand side.
  \[ \mathcal{F} \left( X_{\mathcal{F}} = 0 \sim T, \mu_{\mathcal{F}} = \frac{3}{4} T, \sigma_{\mathcal{F}} = \frac{1}{2} T \right) \]

Here, $X_{\mathcal{F}}$, $\mu_{\mathcal{F}}$, and $\sigma_{\mathcal{F}}$ are the random variable, mean value, and standard deviation of $\mathcal{F}$, respectively, and $T$ is the period of simulation time. Distribution $\mathcal{F}$ models the needs of sending RREQs by MDs. The three scenarios, namely, *left skew*, *balanced*, and *right skew*, indicate that a mass of packet loss occur at time around $0.25T$, $0.5T$, and $0.75T$, respectively.

For distribution $\mathcal{L}$, we consider four scenarios:

- **Spatially middle:** Spatially correlated RREQs are generated in the middle of the simulation.
  \[ \mathcal{L} \left( X_{\mathcal{L}} = 0 \sim T, \mu_{\mathcal{L}} = \frac{3}{4} T, \sigma_{\mathcal{L}} = \frac{1}{2} T \right) \]
- **Spatially late:** Spatially correlated RREQs are generated in the late portion of the simulation.
  \[ \mathcal{L} \left( X_{\mathcal{L}} = 0 \sim T, \mu_{\mathcal{L}} = \frac{3}{4} T, \sigma_{\mathcal{L}} = \frac{1}{2} T \right) \]
- **Temporally middle:** Temporally correlated RREQs are generated in the middle of the simulation.
  \[ \mathcal{L} \left( X_{\mathcal{L}} = 0 \sim T, \mu_{\mathcal{L}} = \frac{1}{2} T, \sigma_{\mathcal{L}} = \frac{1}{2} T \right) \]
- **Temporally late:** Temporally correlated RREQs are generated in the late portion of the simulation.
  \[ \mathcal{L} \left( X_{\mathcal{L}} = 0 \sim T, \mu_{\mathcal{L}} = \frac{1}{2} T, \sigma_{\mathcal{L}} = \frac{1}{2} T \right) \]

Here, $X_{\mathcal{L}}$, $\mu_{\mathcal{L}}$, and $\sigma_{\mathcal{L}}$ are the random variable, mean value, and standard deviation of $\mathcal{L}$, respectively. Distribution $\mathcal{L}$ models the inhibited submissions of RREQs after the RS broadcasts a $g_{\text{ack}}$. To model the spatial correlation of RREQs, the two scenarios, namely, *spatially middle* and *spatially late*, indicate that a mass of correlated RREQs are generated at time around $0.5T$ and $0.75T$, respectively. The similar scenarios (i.e., *temporally middle* and *temporally late*) are also applied to model the temporal correlation of RREQs.

### 5.1. Ratio of inhibited recovery requests

We first evaluate the ratio of inhibited RREQs by BR-LW. To show the effect of $g_{\text{ack}}$ timing, we do not apply the adjustment mechanisms in Sections 4.2 and 4.3. Instead, we let the RS send a $g_{\text{ack}}$ once at fixed time $0.1T$, $0.2T$, ..., and $T$. Note that the RS sends only one $g_{\text{ack}}$ and that MDs still submit their RREQs after receiving a $g_{\text{ack}}$.

Figure 3 shows the ratio of inhibited RREQs under different distributions of $\mathcal{F}$ and $\mathcal{L}$. For comparison, we consider an ideal case where only one MD sends RREQs and other MDs are silent before the RS sending $g_{\text{ack}}$. As can be seen, $g_{\text{ack}}$ timing significantly affects the ratio of inhibited RREQs. The peak (i.e., the maximum ratio of inhibited RREQs) of the ideal case in the spatially middle (respectively, temporally middle) scenario of $\mathcal{L}$ locates at time $0.5T$ because a mass of spatially (respectively, temporally) correlated RREQs are generated at time $0.5T$. In this case, most MDs can find similar requests from the $g_{\text{ack}}$ and thus avoid sending duplicate RREQs. Similarly, the peak of the ideal case in the spatially late (respectively, temporally late) scenario of $\mathcal{L}$ appears at time between $0.7T$ and $0.8T$ because a mass of spatially (respectively, temporally) correlated RREQs are generated at time $0.8T$. However, because the RS will put its predicted future requests in the $g_{\text{ack}}$ if RREQs exhibit temporal correlation, the effect of $g_{\text{ack}}$ timing is less significant in the temporally middle and temporally late scenarios compared with the spatially middle and spatially late scenarios of $\mathcal{L}$.

We then discuss the effect of $\mathcal{F}$ on inhibited RREQs. From Figure 3(a), (c), and (e), we observe that the peak of spatially middle (respectively, spatially late) scenario of $\mathcal{L}$ locates at time between $0.4T$ and $0.5T$ (respectively, $0.7T$ and $0.8T$), which is close to that of the ideal case. In the spatially middle scenario of $\mathcal{L}$, the balanced scenario of $\mathcal{F}$ has the highest ratio of inhibited RREQs (refer to Figure 3(c)). The reason is that most MDs lose a mass of packets at time around $0.5T$ and these packets exhibit high spatial correlation. On the other hand, in the spatially late scenario of $\mathcal{L}$, the right-skew scenario of $\mathcal{F}$ has the highest ratio (refer to Figure 3(e)). Similarly, because most MDs incur serious packet loss at time around $0.75T$ and these packets also exhibit high spatial correlation, sending a $g_{\text{ack}}$ at time $0.75T$ can reduce the most duplicate RREQs.

From Figure 3(b), (d), and (f), we observe that the peak of temporally middle scenario of $\mathcal{L}$ appears at time $0.5T$, which is the same as that of the ideal case. The peak of temporally late scenario of $\mathcal{L}$ appears at time $0.7T$ and $0.8T$, which is close to that of the ideal case. The ratio of inhibited RREQs in the temporally late scenario of $\mathcal{L}$ oscillates because a mass of temporally correlated RREQs are generated late (at time $0.75T$), and thus, the RS may not predict many future requests. Comparing Figure 3(b), (d), and (f), in the temporally middle scenario of $\mathcal{L}$, the right-skew scenario of $\mathcal{F}$ has the lowest ratio. The reason is that most MDs lose their packets in the late portion of the simulation and these packets may be uncorrelated (because a mass of temporally correlated RREQs are generated in the middle of the simulation). However, when most MDs lose their packets in the late portion of the simulation (i.e., the right-skew scenario of $\mathcal{F}$ in Figure 3(f)), the temporally late scenario of $\mathcal{L}$ has the highest ratio because the peaks of distributions $\mathcal{F}$ and $\mathcal{L}$ overlap.

### 5.2. Reduction of packet retransmissions

Using the same setting in the previous section, we then measure the reduced amount of packet retransmissions by...
BR-LW. Recall that the RS will broadcast the packets after sending $g_{ack}$. Thus, the $g_{ack}$ timing can be approximately viewed as the timing to broadcast packets. To show the effect of such broadcasting timing, after the RS broadcasts the packets (at the time of sending $g_{ack}$), we allow MDs to receive unicast packets and submit RREQs simultaneously.

Figure 4 shows the amount of packet retransmissions under different distributions $F$ and $L$. Without BR-LW, the RS always unicasts the requested packets to MDs after receiving RREQs. In the ideal case, we assume that the RS can know the lost packets by all MDs before sending $g_{ack}$. From Figure 4, $g_{ack}$ timing significantly affects the amount of packet retransmissions. The peak (i.e., the minimum amount of packet retransmissions) of the ideal case in the spatially middle (respectively, temporally middle) scenario of $L$ locates at time $0.5T$ because a mass of spatially (respectively, temporally) correlated RREQs are generated at time $0.5T$. In this case, most of the retransmitted packets can meet the requirements of most MDs. Similarly, the peak of the ideal case in the spatially late (respectively, temporally late) scenario of $L$ appears at time between $0.7T$ and $0.8T$ because a mass of spatially (respectively, temporally) correlated RREQs are generated at time $0.75T$. Again, the effect of $g_{ack}$ timing is less significant in the temporally middle and temporally late scenarios compared with the spatially middle and spatially late scenarios of $L$, because the RS
predicts the future lost packets if RREQs exhibit temporal correlation.

Next, we discuss the effect of $F$ on packet retransmissions. In Figure 4(a), the peaks of the three scenarios of $F$ appear at time $0.5T$, which are the same as that of the ideal case. The right-skew scenario of $F$ has the smallest peak, because most MDs experience serious packet loss at time $0.75T$, but most RREQs exhibit high spatial correlation at time $0.5T$. In this case, a $g_{ack}$ can only reflect the spatial correlation of a small number of RREQs, as it is sent early at time $0.5T$. On the other hand, in Figure 4(b), the peaks of the three scenarios of $F$ locate at time $0.7T$ or $0.8T$, which are close to that of the ideal case. The left-skew scenario of $F$ has the smallest peak. The reason is that most MDs experience serious packet loss at early time $0.25T$, but most spatially correlated RREQs are generated at late time $0.75T$.

For the temporally middle and temporally late scenarios of $L$ (i.e., Figure 4(c) and (d)), the peaks of different scenarios of $F$ may not necessary be the same. The reason is that the RS will put its prediction of future lost packets in a $g_{ack}$. However, similar to Figure 4(a) and (b), the right-skew (respectively, left-skew) scenario of $F$ in Figure 4(c) (respectively, Figure 4(d)) has the smallest peak, because $g_{ack}$ can only reflect the temporal correlation of a small number of RREQs.

5.3. Adjustment of $\delta_{var}$

Recall that the RS will send a $g_{ack}$ when $c_{var} \geq \delta_{var}$, which means that the received RREQs may exhibit high spatial correlation. We also analyze how to adjust $\delta_{var}$ in Section 4. In this section, we verify the correctness of our analysis on $\delta_{var}$. The simulation consists of 2000 iterations, each with a period of $T$. In an iteration, we divide the time into 10 segments and check when the condition $c_{var} \geq \delta_{var}$ occurs. We adopt the spatially middle and spatially late scenarios of $L$.

Figure 5(a) shows when the condition $c_{var} \geq \delta_{var}$ occurs in the spatially middle scenario of $L$. From Figures 3 and 4, we find that the optimal time to send a $g_{ack}$ is $0.5T$. We define that the calculation of $\delta_{var}$ hits the optimal value if the time when $c_{var} \geq \delta_{var}$ occurs locates between time $0.4T$ and $0.6T$ (i.e., we tolerate an error of $0.1T$). Figure 5(b) shows the hit rate of $\delta_{var}$, where the exact hit means that $c_{var} \geq \delta_{var}$ occurs exactly at time $0.5T$ and the nearby hit means that $c_{var} \geq \delta_{var}$ occurs at time either $0.4T$ or $0.6T$. As can be seen, in the spatially middle scenario of $L$, the overall hit rate (i.e., the sum of exact hits and nearby hits) is always higher than $80\%$. Besides, the exact hit rate is always higher than $40\%$. The above result shows the correctness of our analysis on $\delta_{var}$ in the spatially middle scenario of $L$. 
5.4. Effect of Handovers

The previous experiments consider the behavior only inside a single RS cell. In this section, we evaluate the effect of handovers. The mobility of each MD follows the random waypoint model, and thus, the occurrence of handovers can be simulated by a uniform distribution. In addition, to measure the effect of handover on the timing of sending $\text{g}_{\text{ack}}$, we allow each MD to send out all of its "unqueried" RREQs to the new associated RS after handovering.

Figure 7(a) and (b) show the hit rates of sending $\text{g}_{\text{ack}}$ because of $c_{\text{var}} \geq \delta_{\text{var}}$ (including both exact and nearby hits) in the spatially middle and spatially late scenarios of $\mathcal{L}$, respectively. For comparison, we also observe the hit rate when there are no handovers. Because the handovering behavior of MDs extends the spatial correlation of RREQs to neighboring RS cells, our lazy-wait operation can help reduce the redundant requests sent from handovering MDs. Therefore, there is only a slight decrease of hit rate caused by handovering MDs. From Figure 7, the decreases of hit rates in the spatially middle and spatially late scenarios of $\mathcal{L}$ are about 4.5% and 9.5%, respectively. On average, the hit rate always exceeds 75% even when...
Request control scheme for data recovery in DVB-IPDC systems

W.-H. Yang et al.

Figure 7. The hit rate of sending gack (due to $c_{var} \geq \delta_{var}$) when there are handovers.

there are handovers, which shows the effectiveness of our BR-LW scheme.

6. CONCLUSIONS

Digital video broadcasting-handheld supports the broadcast service of digital video to handheld devices in a mobile environment, but it may suffer from serious packet loss because of unreliable wireless transmissions. In this paper, we follow the DVB-IPDC architecture by integrating a DVB-H system with a broadband WiMAX network to support the packet recovery mechanism. We have addressed two critical GPL and BDH problems and developed a novel BR-LW scheme to solve these problems. BR-LW exploits the spatial and temporal correlations of recovery requests and efficiently reduces duplicate request submissions while merging retransmissions of lost packets. Simulation results have verified that BR-LW significantly reduces the amount of message transmissions inside a WiMAX RS cell, thereby alleviating network congestion while improving communication efficiency. Furthermore, with mathematical analysis, we have discussed how to adaptively determine the timing for each MD to send its requests based on the channel condition, as well as the timing for each RS to broadcast a group acknowledgement according to the spatial and temporal correlations of received requests.

For the future work, we will further investigate how to improve video quality of MDs by considering some QoS requirements such as delay, jitter, and PSNR in the proposed scheme.

AUTHORS’ BIOGRAPHIES

Wen-Hsin Yang received his BEng and MEng degrees in Information Engineering and Computer Science from the Feng-Chia University, Taiwan, in 1989 and 1991, respectively. Currently, he is a senior engineer of the Information and Communications Research Laboratories at the Industrial Technology Research Institute, and is working toward the Ph.D. degree in Computer Science at the National Chiao-Tung University, Taiwan. His research interests include wireless network, mobile computing, and pervasive computing.

You-Chiun Wang received the Ph.D. degree in computer science from the National Chiao-Tung University, Taiwan, in 2006. He was a postdoctoral research fellow in the Department of Computer Science, National Chiao-Tung University, Taiwan, during 2007–2011. Since 2011, he joined the Department of Computer Science and Engineering, National Sun Yat-Sen University, Taiwan, where he is currently an assistant professor. Prof. Wang served as a guest editor of The Computer Journal (2009), on the editorial board of IARAI International Journal on Advances in Networks and Services (2009–present), and as TPC members of more than 20 communication/computer conferences. His research aims at the design and evaluation of wireless communication protocols and distributed network algorithms. Currently, his research interests focus on broadband wireless communications, sensor & actuator networks, and mobile & pervasive computing. He has published more than 30 academic papers in these fields. He is a member of the IEEE Communication Society.

Bao-Shuh Paul Lin an IEEE Fellow, is a Chair Professor of Department of Computer Science and the Chief Director of Microelectronics and Information Systems Research Center, National Chiao Tung University (NCTU) in Hsinchu, Taiwan since September 2009. He was the Vice President of Industrial Technology Research Institute (ITRI) from 2001 to 2009 and the General Director of the Information & Communications Research Laboratories (ICL), Industrial Technology Research Institute (ITRI) from 2001 to 2009. During the same period, he was also the Director of Committee of Communication Industry Development (CoCID), Ministry of Economic Affairs (MOEA) in Taiwan.

He obtained his Ph.D. in Computer Science from the University of Illinois at Chicago, USA, and has published more than 130 technical papers and reports in ICT fields. In his long professional career, Dr. Lin has won numerous significant awards, has been actively involved in science and technology policy formulation, and helped initiate national programs on System on Chip, Broadband and Wireless Communications, All-IP Networking and Services, and Mobile Digital Life technologies. All these efforts have exerted tremendous impacts on economic and social benefits in Taiwan.
