The Optical Soliton Transmission Amplified by
Bidirectional Raman Pumps with
Nonconstant Depletion
Senfar Wen, Tsun-Yee Wang, and Sien Chi

Abstract—A numerical method is proposed to solve the coupled equations between the soliton and bidirectional Raman pump waves. The pump depletion due to the soliton is obtained without using the constant depletion approximation. With this method, the soliton propagation in a Raman-pumped fiber can be solved accurately. It is found that the constant depletion approximation is valid at a small depletion rate, which requires low soliton power (or long pulsewidth), small material loss, and a short-pump period. In a periodically Raman-pumped fiber, there exists a stable signal energy, which is very sensitive to the pump intensity. We have also studied the stability of the soliton propagation with nonconstant pump depletion. It is found that the stability predicted by nonconstant depletion (NCD) and constant depletion assumption (CDA) are generally different.

I. INTRODUCTION

The optical soliton has been proposed as a dispersionless carrier for high-bit-rate fiber communication systems [1]. In a lossy fiber, the soliton disperses. To compensate the fiber loss in long distance transmission, periodically bidirectional Raman pumps were proposed and proved to be an effective method to compensate the loss and maintain the pulse shape of the soliton [2], [3].

The theoretical study of the system amounts to solve the coupled equations between the soliton and Raman pump waves. In the literature, the depletion of the pump wave by the soliton is often assumed to be a constant or to be ignored [2], [3]. The constant depletion approximation (CDA) is valid when the depletion and the variation of the soliton energy are small and the relative velocity between the soliton and the pump wave is large. For the small relative velocity, the local interaction between the soliton and the pump wave cannot be ignored and changes the pulse shape of the soliton [4]. In this paper, we propose a new numerical method to solve the coupled equations when large relative velocities are involved.

With this method, the pump depletion is accurately predicted and the soliton transmission in the Raman pumped fiber can be studied in a wide range.

II. COUPLED WAVE EQUATIONS AND THE NUMERICAL METHOD

The soliton and the forward Raman pump wave in a fiber satisfy the following coupled dimensionless wave equations [2], [4]:

\[ i \frac{\partial q_d}{\partial \xi} + \frac{1}{2} \alpha_s \frac{\partial^2 q_d}{\partial \tau^2} + \gamma_s(|q_s|^2 + 2|q_p|^2)q_d = -i \gamma_s q_d + iG|q_p|^2 q_d, \]

\[ i \left( \frac{\partial q_p}{\partial \xi} - \frac{\partial q_s}{\partial \tau} \right) - \frac{1}{2} \alpha_p \frac{\partial^2 q_p}{\partial \tau^2} + \gamma_p(|q_s|^2 + 2|q_p|^2)q_p = -i \gamma_p q_p - iG|q_s|^2 q_p, \]

where the variables and the coefficients are normalized in the following way:

\[ \xi = X^{-1} z, \quad \tau = T^{-1} (t - k'_0 z), \]

\[ q_s = Q^{-1} \phi_s, \quad q_p = Q^{-1} \phi_p \]

and

\[ \alpha_s = -k'_0 XT^{-2}, \quad \alpha_p = k''_p XT^{-2} \]

\[ \gamma_s = \frac{\pi n_2}{\lambda_s} Q^2 X, \quad \gamma_p = \frac{\pi n_2}{\lambda_p} Q^2 X \]

\[ \Gamma_s = \gamma_s X, \quad \Gamma_p = \gamma_p X, \quad G = \frac{n_0}{4} \sqrt{\epsilon_0 / \mu_0} g X Q^2 \]

\[ V = (k'_0 - k'_p) XT^{-1}, \quad \kappa = \frac{\lambda_s}{\lambda_p} \]

In (1)-(4), \( \phi_s \) and \( \phi_p \) are the electric field envelopes of the soliton and the forward pump wave; \( \lambda_s \) and \( \lambda_p \) are the wavelengths of the soliton and the pump wave; \( t \) and \( z \) are the time and propagation distance along the fiber; \( T, X, Q \) and \( G \) are the time, distance, and electric field scale factors; \( k'_s, k''_s, k'_p, k''_p \) are the derivatives of the propagation constant \( k \) with respect to the angular frequencies evaluated at \( \omega_s \) and \( \omega_p \), respectively, \( \omega_s \) and \( \omega_p \) are the angular frequencies of the soliton and the pump wave, the first derivative is reciprocal group velocity, the second derivative is proportional to the group dispersion; \( \gamma_s \) and \( \gamma_p \) are the loss coefficients of the fiber at \( \lambda_s \) and \( \lambda_p \); \( n_2 \) is the Kerr coefficient and equals to \( 1.22 \times 10^{-22} (V/m)^2 \).
for fused silica; \( g \) is the Raman gain coefficient which is maximum when the frequency difference between pump wave and the carrier wave of soliton is 440 cm\(^{-1}\) [5]. The maximum gain \( g = 9.75 \times 10^{-14}/\lambda_p \) (m/W) where \( \lambda_p \) is in the unit of microns.

We define the soliton energy as

\[
E = \int_{-\Delta \tau/2}^{\Delta \tau/2} |q_1|^2 d\tau
\]

where \( \Delta \tau \) is the period of \( q_1 \), and forward pump intensity \( I_f = |q_1|^2 \). By assuming the periodical boundary condition and large relative velocity between the soliton and the pump wave, (1) and (2) can be reduced to

\[
\frac{\partial E}{\partial \xi} + 2(G - GL)E = 0 \quad (6)
\]

\[
\frac{\partial I_f}{\partial \xi} + 2 \left( \frac{\Gamma_p + \alpha G}{\Delta \tau} \right) I_f = 0. \quad (7)
\]

Note that \( E/\Delta \tau \) is the soliton’s average intensity. The coupled equations, (6) and (7), can be analytically solved for \( \Gamma_s = \Gamma_p \) [6]. In the following, we consider a numerical method to solve the coupled equations without assuming \( \Gamma_p = \Gamma_s \). Furthermore, both forward and backward pump waves can be solved simultaneously by this method.

From (7), we have the forward pump intensity

\[
I_f(\xi) = I_{fo} \exp \left[-\rho_f \xi \right] \quad (8)
\]

where \( I_{fo} = I_f(\xi = 0) \) is the initial forward pump intensity and

\[
\rho_f = 2 \Gamma_p + \frac{2 \alpha G}{\Delta \tau} \bar{E}_f \quad (9)
\]

is the forward pump loss rate where

\[
\bar{E}_f = \frac{1}{\xi_o} \int_{\xi_o}^{\xi} E d\xi \quad (10)
\]

is the forward mean soliton energy from the initial to the present position. On the right-hand side of the equal sign in (9), the first term is the material loss rate at the pump wavelength and the second term is the pump depletion loss rate. The pump depletion loss rate depends not only on the present soliton energy but also on the history of the soliton as the definition of \( E_f \) in (10) shows. This indicates that the pump intensity at \( \xi \) depends on how the pump wave is depleted from \( \xi = 0 \). To consider bidirectional pumps, we assume the fiber length to be \( \xi_o \) and the backward pump wave is injected into the fiber from \( \xi_o \).

Similarly, we have the backward pump intensity

\[
I_b(\xi) = I_{bo} \exp \left[\rho_b (\xi - \xi_o) \right] \quad (11)
\]

where \( I_{bo} = I_b(\xi = \xi_o) \) is the initial backward pump intensity and

\[
\rho_b = 2 \Gamma_p + \frac{2 \alpha G}{\Delta \tau} \bar{E}_b \quad (12)
\]

is the backward pump loss rate where

\[
\bar{E}_b = \frac{1}{\xi_o} \int_{\xi}^{\xi_o} E d\xi \quad (13)
\]

is the backward mean soliton energy.

Therefore, the coupled equation for the soliton energy and total pump intensity become

\[
\frac{\partial E}{\partial \xi} + 2(G - GL)E = 0 \quad (14)
\]

\[
I = I_{fo} \exp \left[-\rho_f \xi \right] + I_{bo} \exp \left[\rho_b (\xi - \xi_o) \right] \quad (15)
\]

where the coupling is through \( E \) contained in \( \rho_f \) and \( \rho_b \). Because only the energy relation is considered in (14) and (15), the coupled equations can be applied to the Raman amplification problem discussed in [6].

We solve (14) and (15) by the iterative method. From (14), we have the iteration formula

\[
E(\xi + \Delta \xi) = E(\xi) \exp \left[\frac{2(G - GL)}{\Delta \tau} \Delta \xi \right]. \quad (16)
\]

From (9), (12), (15), and (16), with the initial soliton energy \( E_i = E(\xi = 0) \) we obtain the first step soliton energy solution \( E_i(\xi) \). In the first step, \( E_i \) and \( E_{bo} \) are taken to be \( E_i(\xi) = E(\xi) \) and \( E_{bo}(\xi) = E(\xi) \) rather than their original definitions in (10) and (13) because \( E_i(\xi) \) can not be calculated unless \( E \) along \( \xi \) is previously known. \( E_i(\xi) \) and \( E_{bo}(\xi) \) are taken to be their original definitions in the following iterative steps because the approximate soliton energy along the fiber is obtained. Substituting \( E_i(\xi) \) into the iterative equations, we have the second step soliton energy solution \( E_i^{(2)}(\xi) \). The iterative process repeats until the mean error

\[
\epsilon = \left\{ \frac{1}{\xi_o} \int_{\xi_o}^{\xi} \left[ E_i^{(m)} - E_i^{(m-1)} \right]^2 d\xi \right\}^{1/2}
\]

de is the backward pump depletion loss rate that can not be calculated unless \( E \) along \( \xi \) is previously known. \( E_i(\xi) \) and \( E_{bo}(\xi) \) are taken to be their original definitions in the following iterative steps because the approximate soliton energy along the fiber is obtained. Substituting \( E_i^{(m)}(\xi) \) into the iterative equations, we have the second step soliton energy solution \( E_i^{(2)}(\xi) \). The iterative process repeats until the mean error

\[
\epsilon = \left\{ \frac{1}{\xi_o} \int_{\xi_o}^{\xi} \left[ E_i^{(m)} - E_i^{(m-1)} \right]^2 d\xi \right\}^{1/2}
\]

de is the backward pump depletion loss rate that can not be calculated unless \( E \) along \( \xi \) is previously known. \( E_i(\xi) \) and \( E_{bo}(\xi) \) are taken to be their original definitions in the following iterative steps because the approximate soliton energy along the fiber is obtained. Substituting \( E_i^{(m)}(\xi) \) into the iterative equations, we have the second step soliton energy solution \( E_i^{(2)}(\xi) \). The iterative process repeats until the mean error

\[

\]
For periodically bidirectional pumps, it is generally assumed that the pump waves of equal intensity are injected at each distance of $\xi$, into the fiber in both directions that along and against the direction of the soliton propagation. Then the pump intensity at the nth pump period is

$$I = I_n(\exp \{-\rho_p[\xi - (n-1)\xi]\} + \exp \{\rho_p[\xi - n\xi]\}) \quad n = 1, 2, 3 \cdots (19)$$

where $I_n$ is the injected pump intensity. The pump loss rates $\rho_f$ and $\rho_p$ are obtained by the iterative method with the initial soliton energy

$$E_{in} = \int_{-\Delta t/2}^{\Delta t/2} |q(\tau, \xi) = (n-1)\xi_p)|^2 \, d\tau.$$

The coupling loss from a pump period to the next period is neglected for simplicity.

III. COMPARISON WITH THE CASE OF CONSTANT DEPLETION ASSUMPTION

In this section, we will work out some examples with the numerical method shown in last section and check the validity of the CDA. The CDA is valid when [2]

$$\Gamma \xi_p < 1 \quad (20)$$

then the pump loss rates in (19) can be taken as

$$\rho_f = \rho_p = \rho_c = 2\Gamma_p + \frac{2\Delta E_p}{\Delta t} E_{in} \quad (21)$$

where $E_{in}$ is the initial soliton energy at the nth pump period and $\rho_c$ is in fact the pump loss rate at $\xi = (n-1)\xi_p$. When the condition (20) is valid, the attenuation of the soliton is small. This leads to a small variation of the soliton energy when the fiber loss is compensated by the Raman pump. To compensate the fiber loss within a pump period, the integrated gain from the pump waves must be equal to the integrated fiber loss ($2\Gamma \xi_p$). The integrated gain for the nth pump period is $4\Gamma_p I_n / \rho_c [1 - \exp (-\rho_c \xi_p)]$. Therefore, the required initial pump intensity to compensate the fiber loss is [2]

$$I_n = \frac{\rho_c \Gamma_p}{2G[1 - \exp (-\rho_c \xi_p)]} \quad (22)$$

However, the condition (20) is not valid for the interested range of parameters. For the minimum fiber loss 0.2 dB/km and 40 km pump period, $\Gamma \xi_p = 0.92$ does not satisfy (20). By the following numerical examples, it is shown that CDA can be applied well even if (20) is not satisfied.

In the following, we take $\lambda_p = 1.55 \mu m$ and $\lambda_p = 1.46 \mu m$. The fiber losses are taken to be $\gamma_p = 0.3 \text{ dB/km}$ and $\gamma_p = 0.5 \text{ dB/km}$. The dispersion at the soliton wavelength is taken to be 2 ps/km/nm which corresponds to $k_p^2 = -2.55 \times 10^5 \text{ ps}^2 / \text{km}$. Taking $\alpha = 1$, $\eta = 1$, and $X = 10 \text{ km}$ in (4), we have the scale factors $T = 5.0 \text{ ps}$ and $Q = 6.36 \times 10^2 \text{ V/m}$. For the 25 $\mu m^2$ effective cross section of fiber core, the given electric field scale factor $Q$ corresponds to 20.0 mW power scale factor. The other coefficients in (15) and (19) are $\Gamma = 0.345$, $\Gamma_p = 0.576$, $= 0.26$, and $\kappa = 1.06$. The numerical values given here are used throughout this paper except specially specified.

With the initial condition given by (18), $I_n$ given by (22), and the coefficients given above, we solve (17), (14), and (19). Fig. 1 shows the soliton energy $E$ and pump intensity $I$ with respect to distance $\xi$ for $\mu = 1$, $\xi_p = 4$, and $I_n = 3.1683$. It is noticed that the curves for $E$ and $E_p$ are almost overlapped, so are the curves for $I$ and $I_n$.
Fig. 2. Forward and backward depletion loss rates ($\sigma_f$ and $\sigma_b$) in Fig. 1.

$E, (\xi = \xi_p)$ when $\sigma_b < \sigma_e$. In Fig. 2, maximum $\sigma_f = 0.0405$ and minimum $\sigma_b = 0.0245$. It is noticed that the material loss rate $2\Gamma_p$ is 1.152 which is much larger than $\sigma_f$ and $\sigma_b$. This is the reason why CDA is applied well in this case. For

$$2\Gamma_p \gg \sigma_f, \sigma_b$$

(23)

the contribution of the pump loss rates from the pump depletion can be neglected.

Fig. 3 shows an example with the same parameters as Fig. 1 except $\mu = 5$. For $\mu = 5$, $\sigma_e = 0.783$ which is close to $2\Gamma_p$. Equation (23) is not satisfied in this case and it is expected that CDA is invalid. The invalidity can be clearly observed in Fig. 3. Fig. 4 shows the pump depletion loss rates in Fig. 3 where maximum $\sigma_f = 1.168$, minimum $\sigma_b = 0.497$, and $\sigma_e = 0.7815$ which is less than $\sigma_e$. For $\sigma_b < \sigma_e$, it is expected that $E, (\xi = \xi_p) > E, (\xi = \xi_p)$ as discussed above. In Fig. 3, along the fiber $E$ is almost less than $E_c$ every where except at the last section where $E$ is pumped to catch up with $E_c$ and is larger than $E_c$ finally. At the end of the pump period, $E, (\xi = 4) = 10.10$ which is slightly larger than $E, (\xi = \xi_p) = E, = 10$. The soliton energy recovers to its initial energy at $\xi = 1.737$ and 3.995. Fig. 5 shows the envelope of $|q|$ at $\xi = \xi_p$ where the envelope obtained by CDA is also plotted. It is seen that the peak amplitude of the envelope at $\xi = \xi_p$ is slightly larger than the result obtained by CDA. The different evolutions lead to different envelopes at the end of the pump period after propagating several pump periods. We will consider the envelope evolutions in Section V.

The soliton considered in Fig. 1 ($\mu = 1$) is initially with 8.8 ps pulsewidth and 20 mW peak power. The soliton considered in Fig. 3 ($\mu = 5$) is initially with 1.76 ps pulsewidth and 500 mW peak power. The more soliton power, the more pump wave is depleted. High depletion loss rate leads to the invalidity of CDA. For CDA to be valid, the soliton power along the fiber must all be small enough. For large $\Gamma$ and/or $\Gamma_p$, the soliton needs to be greatly amplified from the beginning to endure high loss in the middle of the pump period where the pump intensity is small. The same is true in the case of a very long pump period. These conditions cause high soliton power and high depletion loss rate some where in the fiber and make CDA invalid. Fig. 6 shows the case with the same parameters as in Fig. 3 except $\Gamma_p$ is increased up to 4.032 (3.5 dB/km). In Fig. 6, $2\Gamma_p$ is about ten times greater than $\sigma_e$, but the deviation of the solution from the obtained by CDA is more serious than the deviation in Fig. 3. The soliton energy at the end of the pump period is 9.62.

In this section, only one pump period is considered. After propagating several pump periods, the error resulted
from assuming CDA should accumulate. In the next section, it is shown that the error of the soliton energy at the end of a pump period reaches a stable value. For the practical soliton-based communication system [3], the material loss at soliton wavelength and pump wavelength is about 0.2 dB/km, and the soliton pulselwidth is larger than 10 ps, and the pump period is less than 50 km. It is found that, for these data, CDA is valid for the communication system.

IV. STABLE SIGNAL ENERGY IN THE PERIODICALLY RAMAN-PUMPED FIBER

In Section III, the initial soliton is exactly the fundamental soliton; the pump power is given by (22) which is designed to compensate the fiber loss exactly under CDA; only the propagation in the first pump period is considered. In the followings, we will study more general cases. The initial soliton is not necessary the fundamental soliton or the initial pump intensity is not necessarily given by (22). In this section, we will study the evolution of the soliton energy for several pump periods.

In this section, we solve the coupled equations of the soliton energy and pump intensity, (14) and (19). It is noticed that the energy increment is in fact not necessarily equal to the increment of the soliton energy. The energy increment may be radiated away from the soliton due to the combined effect of the dispersion and the Kerr effect. Furthermore, the radiated wave is amplified by the Raman pumps and shares the energy increment.

In the followings, the coefficients are the same as in Fig. 1. Fig. 7 shows the signal energies at the end of every pump period for various initial signal energies. For different initial signal energies $E_i$, the corresponding initial pump intensities are set to be the same and given by (22) with $E_s = 2$ in $\rho_i \cdot I_s = 3.1682$. In Fig. 1 ($E_i = 2$), at the end of the first pump period, the energy is 1.997. From Fig. 7, it is seen that, after propagating several tens of pump periods, the energy at the end of a pump period reaches the stable value 1.951. For different initial signal energies, the energies all reach the same value. This can be easily realized that the initial pump intensity $I_s = 3.1682$ completely compensates the fiber loss of the signal with $E_i = 1.951$. The stable energy with loss completely compensated is designed by $E_s$. Both the signal with higher energy decays and the signal with lower energy grows to the same stable energy level.

Fig. 8 shows the signal energies at the end of every pump period for $E_i = 2$ and various $I_s$. For $I_s = 3.5$, the signal energy is pumped up to $E_s = 9.985$. For $I_s = 3.1$, the signal energy decays to $E_s = 0.292$. For $I_s = 3.0$, the signal energy decays to zero, i.e., the pump intensity can not compensate the fiber loss of the signal.

If CDA is valid, the relation of $E_s$, and $I_s$ can be obtained by solving (22) where $\rho_i$ is given by (21) and $E_i$ is replaced by $E_i'$, where $E_s$ is the $E_s$ obtained from (22). In (22), the fiber loss of the soliton is completely compensated by Raman pumps. For $\rho_i, \xi_p >> 1$, from (21) and (22) we have

$$\frac{E_i'}{\Delta t} = - \frac{\Gamma}{\kappa G} + \frac{1}{\kappa \Gamma \xi_p} I_s$$

where $E_i'$ is the $E_s$ obtained under this approximation. Because there is no negative light power, $E_i'$ becomes zero if it is negative by (24). Equation (24) shows the linear relation of $E_s$, and $I_s$. From (24), we see there is a threshold $I_s$ to maintain the signal energy. This threshold $I_s$ is designated by $I_s^*$. $I_s^*$ is $\Gamma / \xi_p / G$. The threshold value obtained by solving (14) and (19) is designated by $I_s^*$ and by solving (22) is designated by $I_s^*$. Figs. 9 and 10 show $E_s$ versus $I_s$. The range of $I_s$ in Fig. 9 is from three to ten, while the range of $I_s$ in Fig. 10 is from 3 to 3.5 to show the range that can not be clearly observed in Fig. 9. Near threshold pump intensity, $E_s$ is very different from $E_i$. $E_i'$ coincide with $E_s$ for $I_s > 5$. From the figures, we see $I_s^* = I_s^*$ = 3.08 while $I_s^*$ = 3.06. From $I_s < 4.66$, $E_i < E_i^*$, and, for $I_s > 4.66$, $E_i > E_i^*$. We let the pump intensity as $I_s$, when $E_i = E_i^*$. As discussed in last section, the result shows $\sigma_i < \sigma_0$ for $I_s > 4.66$.

From Fig. 9, it is seen that a slight change of the pump intensity may cause a large change of the signal energy.
V. STABILITY OF THE SOLITON PROPAGATION IN THE PERIODICALLY RAMAN-PUMPED FIBER

In this section, we study the stability of the soliton propagation in periodically Raman pumped fiber with nonconstant depletion (NCD) and compare the results with the case of CDA. With CDA, the stability properties have been studied in [3]. It is found that the stability depends on the ratio of the perturbation period (the pump period $L = \xi_0 X$) and the soliton period $z_o$. The soliton period is defined by

$$z_o = (\pi / 2) \mu^{-2} X$$  \hspace{1cm} (25)

where $X = (T^2 / -k^2)$. It is known that the fundamental soliton solution of (17) with $\alpha = \eta = 1$ and $\Gamma = G = 0$ is

$$q(r, \xi) = \mu \text{sech}(\mu r) \exp \left[ i(\mu^2 / 2) \xi \right].$$  \hspace{1cm} (26)

From (26), the soliton experiences a phase change of $\pi/4$ when it propagates $z_o$ distance. It is found that the soliton is unstable for $L / z_o \approx 8$ because it corresponds to $2\pi$ phase change of the soliton when it propagates $L$ distance and leads to a resonance between the perturbation period ($L$) and the soliton phase. The soliton is stable for $L / z_o << 1$ where the perturbation period is small compared with the soliton period.

The stability property can be represented by the relation of $\delta S$ and $L / z_o$ where $\delta S$ is the ratio of the area change of the soliton at the end of the first pump period and is defined by

$$\delta S = [S(\xi_0) - S(0)] / S(0)$$  \hspace{1cm} (27)

where the area of a soliton is defined by $S(\xi) = \int |q(r, \xi)| dr$.

Fig. 11 shows $\delta S$ versus $L / z_o$ for $L = 40$ km. The numerical values of the parameters are the same with those in Fig. 1 except $\mu$ is varied and initial pump intensity $I_o$ is chosen to make the soliton energy recover at the end of the pump period. In (27), $S(0) = \pi$ nevertheless $\mu$ is varied. In Fig. 11, the dashed curve represents the result obtained by CDA, where the initial pump intensity $I_o$ is given by (22). It is noticed that $L / z_o = 8\mu^2 / \pi$. In Fig. 11, the horizontal axis represented by $\mu$ is also shown. We have known that CDA is valid only when $\mu$ is small as is discussed in Section III. It is seen that the two curves overlapped for $\mu$ less than about 1.5. For larger $\mu$, the two curves are different and there are resonant peaks. The peaks are nearly at the multiples of 7.5 in unit of $L / z_o$ for the curve with NCD. It is noticed that the peaks obtained by CDA are advanced with respect to those obtained by NCD. The resonant peaks can be explained as follows.

In (25), the soliton period $z_o$ is, in fact, only valid in lossless fibers. In a Raman-pumped fiber, the amplitude of the soliton varies along the fiber. If the pulse shape of the soliton is maintained well, from (26) we can define the effective soliton amplitude as $\mu_e = E / 2$ where $E$ is
the average energy of the soliton over the pump period. From (25), the effective soliton period can be defined as

$$z_e = \left(\frac{2\pi}{E^2}\right)X. \quad (28)$$

The resonant peaks occurs when \(L/z_e\) is the multiple of 8 where the phase shift of the soliton is the multiple of \(2\pi\). Fig. 12 shows the average energy of the soliton in Fig. 11 where the result obtained by CDA is denoted by \(\bar{E}_c\). It is seen that \(\bar{E}_c > \bar{E}\) for all \(\mu\). Larger average energy corresponds to shorter effective soliton period or faster phase change. In Fig. 12, \(\bar{E}_c > \bar{E}\) for all \(\mu\) values, which means \(L/z_e\) obtained by CDA is larger than that obtained by NCD. This is the reason that, in Fig. 11, the resonant peaks obtained by CDA are advanced. We define the normalized phase change ratio \(r = L/z_e \pmod{8}\). The resonance occurs when \(r = 0\), which corresponds to the phase shift of the soliton is the multiple of \(2\pi\). Fig. 13 shows \(r\) versus \(L/z_e\). It is found that the resonant peaks in Fig. 13 fit those in Fig. 11 well for \(L/z_e < 40\). It is noticed that the resonant peaks obtained by NCD occur near the multiples of 7.5 rather than 8.0. The resonant peaks occur periodically because in Fig. 12 \(\bar{E}\) is close to \(E_\mu\). It is also found that in Fig. 11 the valleys occur when the phase shift of the soliton is the odd integer multiple of \(\pi\). It is noticed that \(\bar{E} < E_\mu\) for \(\mu > 4.4\) where \(\mu = 4.4\) corresponds to \(I_\mu\) in Fig. 9.

Large \(\delta S\) corresponds to large pulse shape change of the soliton and unstable soliton propagation. To obtain stable soliton propagation, usually the region \(\delta S\) in Fig. 11 near and below zero is chosen. Fig. 14 shows the envelope of the soliton with \(\mu = 1\) at \(\xi = 200\) (2000 km) and that obtained by CDA for comparison. It is seen that the envelopes of the two solitons are almost the same. For smaller \(\mu\), not only the envelopes are more alike, but also the pulse qualities are better and the noise waves are reduced.

The other region in Fig. 11, the large positive \(\delta S\) region, corresponds to unstable soliton propagation. The resonant peaks in the region corresponds to the extrema of the unstability of the soliton propagation. The resonant peaks of the two curves are different. In some cases, the peak of one curve corresponds to the valley of the other curve. Figs. 15 and 16 show the evolution of the soliton with \(\mu = 5\) for NCD and CDA, respectively. \(\delta S\) is at the valley for NCD and at the peak for CDA. It is seen that the soliton calculated by NCD can maintain its pulse shape well until 1120 km (\(\xi = 112\)), while the result calculated by CDA is only 520 km. On the contrary at \(\mu = 4.82\) where \(\delta S\) is at peak for NCD and at valley for CDA,
the soliton calculated from CDA can be maintained better. The propagation distance over which the soliton with CDA can still maintain its pulse shape is 640 km, while that with NCD is only 440 km.

VI. CONCLUSION

In this paper, we have shown a numerical method to solve the coupled equation of the soliton and Raman pump waves. In this method, we only assume a large relative velocity between the soliton and Raman pump wave. For bidirectional Raman pumps, both forward and backward pump depletion rates can be obtained. In literature, they are assumed to be constant. It is found that the constant depletion approximation is valid for small depletion rate, which requires low soliton power (or long pulsewidth), small material loss and a short pump period.

In periodically Raman-pumped fiber, a stable signal energy exists. The signal energy is the total energy that includes the soliton energy and the noise energy. The noise is radiated out from the soliton due to the perturbation of the combined effect of the fiber loss and Raman gain. The relation of the stable signal energy and pump intensity is obtained. It is found that stable signal energy is very sensitive to the pump intensity. A slight change of the pump intensity may cause a large change in the signal energy. The stability of the soliton propagation in the Raman-pumped fiber is also studied. It is found that the stability predicted by NCD and CDA are generally different.
